urethral caliber is then encroached upon and the balance existing between the expulsive force of the bladder and the friction of the stream along the urethra is disturbed and symptoms follow. A constant irritation and inflammation is then kept up by this beginning contraction as I have pointed out.¹ I referred then to the mechanical obstruction, the chemical irritation, and to a mechanical irritation and "by mechanical irritation I mean the encroaching upon and squeezing of the nerve-endings in the mucous membrane by the newly formed fibrous tissue." As the urethra is claimed by Civiale to possess a sympathetic sensitiveness independent of the local, then through the third agent—mechanical irritation—we ascribe as being the principal, if not the entire cause, when he refers to this sensitiveness "being aggravated it may awaken sympathetic response in every organ and function of the body." Aside then from the suffering and inconvenience attendant upon the disease *per se* we have a grave complication, or result, in stricture as evidenced by the simple case No. 715 reported above, in which, even the act of urination should not have been interfered with to a noticeable degree. This case was an example in which the mechanical irritation "awakened the sympathetic response" and produced the symptoms he had and relief began as soon as the hard, fibrous tissue was divided which allowed of the relaxation of each fiber and a consequent inability to produce pressure. The question arises then why we do not have these or similar responsive symptoms in every case of stricture, and I would answer that we do almost invariably and more especially if the stricture be an annular one and located in the fossa navicularis. It is rare that we have a stricture within one-half inch of the meatus that we do not have symptoms other than the interference with the passage of the urine. To determine the validity of this point I made several examinations and found, that out of 194 patients examined for stricture, that condition existed in 184. Some of these had discharges at the time and others were only suffering from the resultant conditions of that discharge, but all had symptoms pointing to a urethral stricture, otherwise the examination would not have been made.

A word here may not be out of place in reference to the treatment of chronic gonorrhea at this resort and why it is successful. It is not an uncommon occurrence, in fact a very frequent one, for visitors who have been here a few days, using the waters, to call the attention of their physician to a slight urethral discharge, making the statement, that several weeks or months before they had had an attack of gonorrhea, but thought it entirely cured. In others a slight, but noticeable discharge would be increased. I would account for this by the well-known fact that these waters are stimulating to the urethra and during the first few days of its internal use decidedly so. In an acute case the hot water is to some extent harmful, although that from many of the cold springs is very beneficial as soothing diluents. It is also an established fact, that a low-grade inflammation, such as we have in gleet, demands a stimulant to bring about a healthy reaction, and this we get, in various degrees, from the use of the hot waters, by increasing or decreasing the amount used as the case may demand, and to this then is added the local treatment.

¹ See discussion of urethral stricture in History of the Hot Springs of the Philadelphia Medical Journal, Vol. 1, No. 1, 1900, p. 128.

In taking up the remaining subject, that of syphilis, we will begin by giving Charts IV, V, and VI.

The average age at which syphilis was contracted	25.7	

In comparing Chart IV with the similar one for gonorrhea we see that infection begins at the age of 15 instead of 10, it reaches its greatest number at 22 instead of 18, and is also continued to a more advanced age, 65 instead of 57. The ratio we find to be pretty constant all the way through. The reason for this being so, can be accounted for by gonorrhea being of more frequent occurrence; by boys in their first amours being led by the bolder women that frequent the streets. These women take little care of their persons and practically all have a partially cured gonorrhea, while they do not all have syphilis, being trained in the art of observing their victims for their own protection, which can be done better ordinarily in syphilis than in gonorrhea, hence they become sources of great danger. Later, too, the men become more bold and make victims of comparatively innocent parties, and these women from ignorance, and real or assumed modesty, are unable to protect themselves, hence contract syphilis easily and likewise distribute it as easily among other "special friends." Care also in postamour ablutions and a lesser susceptibility of the urethra to the action of the gonococcus in the older subjects has its influence.

In Chart V is given the most important data we have to offer. When we glance at it and see the great number who have had syphilis for so many years, and to know that the greater proportion of them were still suffering from the activity of the disease, it is, to say the least, discouraging. I am not willing to say that they were all suffering from syphilis direct, many were

suffering from the effects of its poison, possibly more from the effects of its irrational treatment, and still others from the thoughts of having had it. To at once appreciate the magnitude of the working forces of this disease, let us make some deductions from the cases I present, taken as a standard. There were 799 cases whose average time of battling with the infection was over 3 years and 7 months. Reduce this to years for the whole number and we have a little over 2,916 years. Again, taking the data furnished by Gihon, who estimated that there are at one time 2,000,000 cases of syphilis in the United States, and from this at the same ratio of existence in each case of the disease, we have 7,300,000 years; and as Buret has traced the disease back nearly 7,000 years, and we come to compute for

the whole world for that length of time including the terrific ravages of the plagues, we find ourselves completely lost in the immensity of numbers—and yet this little something that has given so much trouble and for such a great length of time is not even known. By stealth these victims keep the knowledge of their suffering from the public gaze, but that monstrous reaper—tuberculosis—almost pales into insignificance in comparison. After years of constant attack of the poison of syphilis upon the system, whatever it is, it is true its forces are depleted and attenuated, but likewise are the opposing forces in the human victim, and we have left a constitution eminently fitted for furthering mortality.

The fact, of course, is to be considered that many of the older cases we see here are the exceptions, and that we must not lose sight of the fact that there are hundreds who never see and apparently never know of any inconvenience from the disease a few months after infection, and it will again be necessary to keep in mind the class of patients reported. Neglect in the early and proper treatment, continued over a sufficient length of time, even in the absence of symptoms, is so often neglected by these people that it becomes a greater factor of harm than in private practice.

I also tabulated the special features of those cases that had had the disease for 4 years and over, to see what the prevailing ailments might be, and while I found a great variety of results there were special lines very noticeable, and at the same time convincing proof that the man who contracts syphilis may indeed be impressed with the idea that his troubles in life have well begun, and as time goes on, he too often is further made to believe, from experience, that they increase as he grows older. Among these features were gummatous ulcers in various locations, indefinite pains, rheumatism, anemia, many bad stomachs, necrosis of bone, rupia, and a point noticed particularly was the number in whom the glands were markedly enlarged, even for a period of 8 or 10 years or more. Ulcers were seen in great numbers, and small multiple sores well distributed over the entire body were much more frequent than I had been led to believe they would be. The points other than enlarged glands, weakened stomachs, anemia, and indefinite pains will be passed by, merely having been mentioned.

A marked glandular enlargement, noticeable several years after infection, is quite frequent and possibly more so among these patients than in private practice, and is probably due, when dependent upon this disease, to the fact that treatment in the early stages is not persisted in until they are reduced, they then become permanently enlarged from a new growth of interstitial fibrous tissue which resists, to a great extent, all treatment. These glands are not of especial value as a diagnostic sign, so late in the disease, in determining whether it is still present or not, and, of themselves, do not demand treatment. In the laboring classes the inguinal and epitrochlear glands are often enlarged, hard labor itself being the only tangible cause, and the former are most always permanently enlarged in patients who have had protracted attacks of gonorrhea.

The other conditions—weakened stomach, anemia, and indefinite pains—follow each other naturally. It is the custom of many physicians to prescribe potassium iodid in the early disease, even in large doses, along with mercury in some form as a routine treatment. If this is not done, often the patient him-

self, especially the dispensary patient, goes to the druggist and obtains a bottle of iodid and begins to treat himself. He has heard of what a wonderful walking barometer he may become, by mercury being deposited in his bones, should he take that drug. He soon finds by experience that potash will produce pimples on the skin, and concludes at once that it is "ridding the system of bad blood." Every tramp you see basking in the sunshine on the mountainside has a small pocket mirror which he consults frequently to see the progress of his pimples. Like the ancient Sun Worshipers they worship them because they can see them. A few weeks or months after experiencing this eruptive process for a considerable time, some real or imaginary symptom causes him to reproduce it. Again and again this is repeated until his stomach begins to rebel under the weight of the *potash habit*. From a generally inactive stomach, the proper amount of nourishment is not supplied to the system and anemia follows. In the trail of anemia may then revive the latent forces of syphilis, and attack any organ or tissue of the body. The mental capacity is lessened, the nerves assert themselves, and we have the *indefinite pains* spoken of above. These pains are indefinite as to intensity, location and time of occurrence. The intensity of the pain varies very much, but is usually not severe and is aching in character; they are inconstant as to their persistency in any one part; they are not influenced to any extent by the hour of the day, but the changes in the weather have much to do with their occurrence and severity. That the potassium iodid is the prime factor indirectly in developing these conditions I do not doubt, but that it is a cause direct, I do doubt, for mercury will relieve them; however, this may be due to some extent to its rapid tonic action on the blood in this condition. By avoiding mercury and by abusing the use of the potassium iodid this condition is brought about, yet is always, by the patient, attributed to mercury. He connects it with mercury from the fact that the pains are more severe during damp and cloudy weather. The pain often seems deep-seated, his bones ache and he imagines the barometric state has been reached. He comes here to bathe for the purpose of getting rid of the mercury, of which he has taken a little perhaps years before, but always includes his usual course of potassium iodid, which seems as essential to him as does the cocktail to the habitual rounder. Finally, when he is disappointed at not obtaining relief, he consults a physician and usually refuses to take mercury, but when it is given to him secretly he is relieved. This may be an example of *similia similibus curantur*, but I think instead, it is a case of syphilis meeting with its proper antidote. Where we may possibly see one injured by the use of mercury we see hundreds that are injured irreparably by the uncalled for and irrational use of the potassium iodid.

Health of the Army.—The Surgeon-General has received a report from Col. Greenleaf, chief surgeon of the division of the Philippines, regarding the health of the army in that locality. The report which was dated Manila, January 15, 1901, showed that at that time the strength of the command was 67,415, and the percentage of the sick was 7.49. The consolidated weekly report of hospitals in Manila and the military hospitals in the division shows 2,400 sick, of which 390 were cases of malaria, 1 fever, 326 dysentery, 258 wounds and injuries, etc. There were 83 deaths among the troops during the month ended January 15.

The Oxytocic Action of Lumbar Injection of Cocain.—Since the startling innovation of lumbar puncture with subarachnoid injection of cocain for purposes of general anesthesia the medical journals have from time to time published reports of cases so operated upon. This method of anesthesia has especially received support on the continent and by the French surgeons in particular. The records of Tuffier, who has probably experimented on the subject more extensively than any other individual operator, are not encouraging. The very decided mortality attendant upon cocain-injections into the spinal canal would not warrant the general adoption of such an apparently dangerous method of anesthesia save in those cases in which other anesthetics should be contraindicated.

Following shortly upon the general surgical use of lumbar injections of cocain came the suggestion of its employment in labor for purposes of anesthesia. Under the action of the drug the labors were found to progress without suffering on the part of the patients and, according to the published reports, without any evil consequences to mother or child. It was noted, however, by several of the experimenters that there developed a tendency to uterine and abdominal inertia, the former from a direct benumbing action on the uterine muscles and the latter probably as a consequence of the loss of suffering on the part of the patient who experienced no stimulus to bear down and thereby hasten the delivery of the fetus. Thus, Marx, of New York, in a series of 40 cases thus treated, was compelled to hasten delivery by the application of forceps in 16 instances,—an unusually high percentage of operative cases.

Recently, however, the distinguished French obstetrician and gynecologist, Doléris, has presented papers before various well-known societies, including the Académie de Médecine, the Paris Society of Obstetrics and Gynecology, and the Medico-Chirurgical Society of Paris, in which he strongly advocates the use of lumbar injections of cocain as an efficient oxytocic. Coming from such a source, and directly antagonizing the former published records as to the action of the drug thus administered, these communications must elicit considerable interest the world over. Doléris states that while anesthesia is complete, there is no diminution in the intensity of the uterine contractions, which are of rapid occurrence and normal duration, and

produce a speedy and progressive dilatation of the os with normal obliteration of the cervix. After delivery of the fetus has been accomplished in these cases, the uterine retraction and contraction are normal. This was especially noted in a case of Cesarean section for pelvic contraction, which was performed by Doléris on the eighth of October last, the Säger operation being selected and the results being all that could be desired. In fact, Doléris remarks that in no other Cesarean operation performed by him had he noted such complete and persistent uterine contraction, and he further suggests that in cases of labor in which the operation of version would have to be performed, this firm contraction resulting from the action of the drug might contraindicate its use.

Kreis, however, who had performed version under cocain anesthesia secured through lumbar puncture, experienced no difficulty from this source. Contrary to the general experience of the experimenters thus far Doléris would suggest the use of cocain-injections as the proper course to pursue in the treatment of uterine inertia. He maintains that even in small doses of one centigram of the cocain solution there follows a positive action on the motor uterine nerves whereby efficient labor-pains are induced. He even goes so far as to say this might eventually become the accepted method of induction of labor.

Remarkable as are these statements of the eminent French obstetrician we feel that without further confirmation from other equally reliable sources this method of treatment cannot conscientiously receive the endorsement of obstetricians any more than could the suggestion of Lawson Tait, published immediately prior to his death, that Cesarean section should be adopted as the proper treatment for placenta previa. With the evident mortality that has attended the use of subarachnoid injections of cocain in general surgery one would hardly feel justified in exposing his parturient patients to risks that legally as well as morally would not seem warranted. The profession will await with interest the future developments in this line of experimentation.

The Differential Determination of Human Blood from that of Animals.—The determination of a satisfactory method of differentiating human blood from that of animals is a problem of recognized medico-legal

importance. The spectroscopic examination will prove merely the presence of hemoglobin, but will furnish no clue as to the derivation of the blood. The character of the crystals of hemoglobin varies in different animals, but from a medico-legal point of view, this difference cannot be utilized owing to the fact that a considerable quantity of fresh blood is required. The study of the relative differences between the red blood-corpuscles is comparatively fruitless, for within the limits of size of a human red blood-cell there might be included those of the dog, rabbit, and perhaps other domestic animals. Equally uncertain is the test of the time of coagulation of fresh blood. We are indebted to a French observer, Bordet, for a decidedly practical advance in this direction. In 1898 he showed that after injecting into an animal the defibrinated blood of a different species there were developed in the blood of this animal two substances which he termed *agglutinin* and *hemolysin*. The former of these possesses the property of agglutinating the red cells; the latter disintegrates them. Their peculiar properties are exerted only upon the particular blood with which the animal was inoculated. Following this investigator Uhlenhuth, of the Institute of Hygiene of the Faculty of Medicine of Greifswald, performed a series of experiments upon rabbits, first with bovine blood, then with human blood. He injected into the peritoneal cavity of these animals 10 cc. of defibrinated beef blood, and after five injections the serum of the rabbits' blood was so modified as to cause agglutination and to possess hemolytic properties towards the blood of beef exclusively. He then prepared a series of dilutions of human blood and the blood of nineteen different animals, principally the domestic animals. This was allowed to settle, or was filtered and an equal quantity of saline solution was added to each tube. By means of a pipette, six to eight drops of serum of the rabbit, which had received the injections of the defibrinated beef blood, were added to each tube. In all the tubes save the one containing the blood of beef, the liquid remained absolutely clear, but in the tube containing this blood a flocculent precipitate was formed. The same experiment was repeated with the serum of rabbits which had received injections of defibrinated human blood. It was found upon adding a dilution of human blood to tubes similarly prepared that no precipitate was formed except in that containing the serum of the rabbit which had received the injections of human blood. More recently and independent of Uhlenhuth's work, Wasserman and Schütze, of the Institute for the Study of Infectious Diseases in Berlin, pursued similar investigations. At intervals of two days they injected into the peritoneal cavity of rabbits 10 cc. of human blood-serum deprived of its cellular elements. After five or six injections the animals were bled from the carotid. The blood was collected carefully and allowed to separate at low temperature. Upon adding to the serum of the rabbit a weak solution of

human blood diluted with physiological salt-solution, or distilled water, a precipitate was immediately formed. These observers declare that the action of the serum of rabbits so treated is specific, for the reaction is not observed with any other than human blood. Uhlenhuth has found that this specific reaction may be obtained with a drop of blood which had been dried for four weeks upon a board.

We hope that these investigations may have an important medico-legal bearing and may furnish us finally with an absolute, as well as thoroughly practical, differential test. A résumé of these experiments from the pen of L. Cheinisse appears in *La Semaine Médicale* of February 27, 1901. Bordet's original paper was published in the *Annales de l'Institut Pasteur*, October, 1898; Uhlenhuth's in *Deutsche medicinische Wochenschrift*, February 7, 1901; and the paper of Wassermann and Schütze will be found in *Berliner klinische Wochenschrift*, of February 18, 1901.

The Crusade Against Cigarettes.—According to *The Outlook*, measures directed against the sale of cigarettes have occupied much attention in the various State Legislatures this past winter. One of the most radical measures is that adopted by the lower house of the New Hampshire Legislature. This law provides that hereafter no person, firm or corporation shall make, sell or keep for sale any form of cigarette. It makes even the gift of a cigarette to a minor a misdemeanor. The penalty is a fine of ten dollars for a first offense and fifty dollars for any subsequent offense. The magazine from which we quote says that this act is a sample of those which have been presented to most of the State Legislatures. It seems that eleven States have already passed laws against the cigarette, and that only two States—Louisiana and Wyoming—have not given the subject some attention. These measures seem to win support very largely from the fact that there is such a widespread belief that this particular use of tobacco is especially prevalent among boys and young men, and that it is doing incalculable injury to many of the rising generation. Even among legislators who are themselves smokers it is not difficult to win support for such bills, because they put this abuse on the same plane as the sale of liquor to minors. The more rational reformers who are frankly opposed to the use of cigarettes (not only by minors but also by adults, and especially by women) will very much doubt the expediency of such stringent legislation as that adopted in New Hampshire. It is notorious that sumptuary and prohibitory legislation generally over-reaches itself, and in the end falls a dead letter. We ourselves doubt whether men and young society women can be legislated out of the use of cigarettes. We even believe that such a law, when aimed at adults, is essentially tyrannous and that it is a specimen of the worst form of paternalism. In the case of minors the question is, of

course, different; and the attention of law-makers should be limited to devising means to stop the sale of cigarettes to this class, just as the law aims to stop the sale of liquors to it. The best preventive after all is a sound public sentiment, and this can be directed against adults of both sexes, as well as against boys. There is doubtless a prejudice abroad against cigarettes, but it seems to be based in part upon nothing higher than the dislike which most normal persons have for the fumes of burning paper.

The Antitoxin-Treatment of Diphtheria.—While it is within the bounds of moderation to state that the mortality from diphtheria has been reduced about one-half in consequence of the employment of the antitoxin in treatment, it is generally recognized that the best results are obtained the earlier in the progress of the disease the treatment is instituted. It has also been learned that maximum doses should be injected at once and be repeated in accordance with the indications in the individual case. Certain differences are observed, also, if the cases are classified in accordance with their character. Thus, Escherich (*Berliner klinische Wochenschrift*, 1901, No. 2, p. 38) recognizes three varieties of diphtheria: (1) The local variety, with slight susceptibility to the action of the toxin, and locally limited superficial predisposition; (2) the progressive variety, with slight susceptibility to the action of the toxin, extensive superficial predisposition, and extension to the air-passages; (3) the toxic-septic variety, (A) with marked susceptibility to the action of the toxin, and circumscribed local lesions (hypertoxic variety), (B) with marked susceptibility to the action of the toxin and local mixed infection, (a) with pyogenic cocci (phlegmonous, necrotic, septic variety), (b) with putrefactive processes (fetid variety), (c) with gangrene (gangrenous variety), (d) with the hemorrhagic diathesis (hemorrhagic variety). An analysis of the cases under observation, classified according to this plan, shows that in the preantitoxin period, from 1890 to 1894, there were treated 115 cases of diphtheria, with a mortality of 45.2%. Of these cases, 30 were classified as localized, 74 as progressive (croup); 11 as septic-toxic, the mortality in each group being, respectively, nil, 55.4% and 100%. In the succeeding, antitoxin, period, from 1894 to 1899, there were treated 1,147 cases, with a mortality of 13.08%. Of these, 593 were localized, 378 progressive, 176 septic-toxic, and the mortality was, respectively, 0.17%, 19.58%, and 42.62%.

Anti-Diphtheritic Serum.—In a recent article in the *Münchener medicinische Wochenschrift*, January 15, 1901, by Trumpp, certain facts regarding the action of anti-diphtheritic serum are stated that are not generally known, and, if true, are of considerable importance.

Trumpp had under his care a child to whom 3 doses, each containing 1,500 units, were given without the

least influence upon the rapid course and fatal termination of the disease, and as the first dose was given at the very commencement of the symptoms, it seemed to him that there should be some reason why in this particular instance the effect had been so entirely negative. There could be no doubt about the diagnosis because the organisms were found in considerable numbers, and there was no reason to suppose that mixed infection existed, for nothing in the bacteriological examinations or in the clinical course of the disease suggested this. Then it occurred to him that possibly the serum might be at fault. Upon inspection, however, it seemed normal, and there was no local reaction at the point of injection. On examining the label, however, he found that the serum had been prepared 10 months previously, and he suspected that possibly it had lost its potency on account of prolonged keeping; but upon inquiry he found that it was still legally efficient, as it was not yet time to retire it in accordance with the German law upon this subject. He, therefore, applied to the "Höchster Farbwerke," where the serum had been prepared, and received a reply from Dr. Libbertz, in charge of the protective serum department. In this Libbertz states that although it is true that serums do diminish in effectiveness after keeping, this diminution occurs in the first two or three months and is probably due to the action of the antiseptics. Later, they can be kept for years without any impairment of their potency. He also stated that in view of this diminution it is customary to mark the serums with a rather lower potency than they actually possess so that the minimum value always exceeds that stated upon the label. In conclusion, however, Libbertz states that in consequence of the impairment in anti-diphtheritic serum, quantities of it are from time to time withdrawn from commerce.

Trumpp very pertinently inquires whether these experiments upon which the first statements are based, were made upon animals or human beings? and further, what conditions give rise to the loss of potency?

The whole question is an exceedingly interesting one, and of the gravest importance to clinical medicine, because upon the effectiveness of the first dose of serum depends, in all probability, the outcome of the case.

It is a pity that some of our bacteriological laboratories in America, which, on the whole, produce such a relatively small amount of original work, can not thoroughly thrash out this subject.

The Value of Alcohol as Food.—This subject is apparently one that will not stay settled. Not long ago Prof. Atwater thought he had settled it for a while when he stated that alcohol is a food in the sense that it supplies energy to the body, although not in the sense that it goes to form tissue. This, in fact, has been the teaching of physiology, if we mistake not, for

a good many years. Now M. Chauveau, a French physiologist, reports a series of experiments which he had made, and which, he claims, tend to prove that the value of alcohol as a food has been much overestimated. He thinks (*Revue Scientifique*, January 12 abstracted in the *Literary Digest*) that he has established that very little energy, if any, is derived from ingested alcohol. We are not prepared to criticise M. Chauveau's opinion, but we cannot help suspecting that a little of the uncertainty that clings to this subject comes from the ambiguity of this term "energy." His object, apparently, was to discover whether in the case of a laboring man the muscles are caused to contract by deriving the necessary energy from the combustion of alcohol. This seems to us to be somehow a rather inadequate statement of the question. We should suppose that a muscle's "energy" was not derived from an outside source but from its own inherent nutritive function. For the sustaining of this nutritive function it, of course, requires a food from a source outside of itself. M. Chauveau seems to think that ingested alcohol can participate only in a feeble degree in this process. He, therefore, thinks that alcohol is not a food so far as the production of force is concerned, and its introduction into the ration of a worker is a physiological contradiction. He contends also that the organism, even when not actively at work, does not use alcohol as a food in any of its physiological processes. The results of all experiments, he says, show this; especially the enormous deficit in its combustion shown by its elimination, especially through the lungs. After all, these profound and somewhat obscure physiological speculations do not invalidate the conclusions of practical clinical observers that in some particular way alcohol has distinct value as a therapeutic agent. Call it a food, an energy, or merely a stimulant, its place is probably quite definitely fixed in practical therapeutics.

A Study of British Genius.—Mr. Havelock Ellis has been publishing in the *Popular Science Monthly* a paper on this subject which contains some items of special interest for medical readers. As a study in heredity and environment the paper has, of course, a general interest for the limited class of physicians who concern themselves with these topics; but it also contains things here and there which challenge the attention of all medical men because of what we may call a personal or professional bearing. Mr. Ellis' first care, of course, in making a statistical study was to select his material, and it is right at this point that he excites criticism. He proceeded, according to a law of his own, by picking from the "Dictionary of National Biography" the names of such Britons, in all fields of mental activity, as seemed to himself to have been endowed with genius. He finds that the doctors make an "unexpectedly small group." He discovered that Great Britain has produced no fewer

than 859 men of more or less genius (according to Havelock Ellis and the aforesaid "Dictionary"), but in this goodly sized group there were only 7 doctors. This alleged fact is all the more depressing because the group is not confined to moderns but goes all the way back to St. Boniface and Duns Scotus. These 7 doctors are Linacre, Caius, Mead, Pott, Sydenham, Cheselden, and Cullen. We know not what assistance Mr. Ellis had, if he had any, in making this selection, and we must acknowledge that these names are fairly representative, but we cannot see by what principle of exclusion the names of Harvey, Jenner, John Hunter, and Lister, not to mention a few others, were left out of this list of medical men. Mr. Ellis explains that eminent physicians sometimes win fame in the domains of pure science, and cannot be strictly classed with their profession. This was true of Huxley, who is not included anywhere in the lists, but it certainly was not true of the four just named, all of whom are listed by Mr. Ellis with the men of science. Sir Thomas Browne is placed among the men of letters, but his profession will not let him go without a remonstrance. Erasmus Darwin also was an M.D. We protest that all this is unjust to the medical profession, and goes far to invalidate Mr. Ellis' conclusions.

Among these conclusions is one respecting the percentage of 640 of these men of genius. But 2.9% of them had physicians for fathers, while 12.5% were the sons of clergymen, and 5.4% were sons of lawyers. The inferences to be drawn from these figures are somewhat problematical, but the figures should not be taken to imply (as Mr. Ellis might lead one to do) that doctors do not procreate as brainy sons as do clergymen and lawyers. This inference, based on such figures, would be preposterous. The social status and customs in England probably influence these results. This is shown by the fact that the church outnumbers all the other professions together—law, medicine, and the army—in this matter of begetting men of genius. It is curious, perhaps, that not an eminent doctor was the son of a doctor, although army officers and clergymen are often the fathers of sons eminent in these respective professions. But Charles Darwin was the son of a physician, as was also Landor, the man of letters—at least, so we infer from Mr. Ellis. Edward Forbes, the naturalist, was a student of medicine. In the case of Oliver Goldsmith, who was a physician, we perhaps have no right to set up much of a claim.

Medical College Libraries.—There can be no question that a well-stocked medical library is a most important adjunct to a medical college. Neither is there any doubt that such a library should be housed in a convenient and attractive way so that medical students in their odd and leisure hours would feel inclined to patronize it. A collection of old medical books in a cold and barren room is not the ideal for such a library. We learn from the *Jeffersonian* that the

library in Jefferson Medical College (which attains a proper ideal) is thoroughly appreciated by the students. This is evident from the rapid month-by-month increase in the number of books taken out. The library report shows an average of more than 50 volumes a day for each working day of the month, while the largest number was 100 on one day. This indicates the cultivation of a studious habit and the formation of a literary taste which from some standpoints are just as important as the results obtained from routine work. In our great universities the library is properly made the central figure of the campus; it is the central luminary about which the intellectual life of the university revolves. The University of Pennsylvania well supplies this want, while at Harvard and Princeton it is as good as giving an education to give a student free access to the University Library. Our medical colleges would all be fortunate to have such advantages.

"The Clinical Value of Astereognosis, and its Bearing on Cerebral Localization."—(Abstract of Dr. Walton's paper before the Philadelphia Neurological Society, February 25).

The writer dwelt on the importance of testing the stereognostic sense in cerebral disease. Impairment of this sense is not rare. Lasting astereognosis is common in hemiplegia. (Abba found $\frac{1}{3}$, Dercum nearly $\frac{1}{3}$, the writer $\frac{1}{3}$.)

Four cases were reported of lesion in the Rolandic area, three with operation. Astereognosis was present in all with no loss of pain or temperature senses, and in only one case, slight impairment of touch sense. In one case motor paralysis, previously limited to the lower extremities, spread after operation to the hand which then became astereognostic. The astereognostic patient cannot tell, if the foot is affected, whether the pencil is applied transversely to the sole or only the point is used, though the touch sense may be normal.

These cases, with others reported, tend to show that the Rolandic region is an important seat of the stereognostic sense. This assumption is not contradicted by the numerous cases reported of Rolandic injury unaccompanied by sensory loss, for in such cases the examination has not, as a rule, included the stereognostic sense. When this sense has been tested in such cases it has been found defective.

In view of the strong evidence for both the Rolandic region and the parietal lobes and gyrus fornicatus as sensory areas it seems desirable to reconcile, if possible, the views of Mills and Dana. The writer suggested a theory adaptable to clinical experience and analogous to a mechanism already accepted, namely that of language.

In studying this question we need not limit the number of neurons involved, for it is as logical to suppose these processes complicated as to assume that they are simple. The theory suggested included:

1. Structures receiving simple cutaneous sensations.
2. Centers for appreciating the qualities of the objects touched (corresponding to the center for mind vision).
3. Kinesthetic centers assembling these and other sensory stimuli. The centers of the third order are probably seated principally in the postcentral gyrus. For diagrammatic purposes the writer placed the centers of the lower order in the parietal lobes and gyrus fornicatus for the upper and lower extremities respectively. Astereognosis might result from lesion in the parietal region through disturbing the mental picture.

The fibers conveying muscle sense probably follow a more direct course from the internal capsule or thalamus to the kinesthetic centers. These centers may represent the aggregation of associative memories stimulating so-called voluntary movements. Though the whole hemisphere may take part in mental processes, lesions in certain regions are perhaps specially liable to disturb these processes when exercised in certain directions on account of the aggregation of associative memories. From this point of view cerebral localization is not altogether incompatible with the psychology of Loeb.

Reviews.

Therapeutics: Its Principles and Practice. By HORATIO C. WOOD, M.D., LL.D., Professor of Materia Medica and Therapeutics, and Clinical Professor of Diseases of the Nervous System in the University of Penna., etc. Eleventh edition. Remodelled and in greater part rewritten by Horatio C. Wood, M.D., and Horatio C. Wood, Jr., M.D., Demonstrator of Pharmacodynamics in the University of Pennsylvania. 8vo, pp. xxxi, 850. Philadelphia and London: J. B. Lippincott Co., 1900.

Dr. Wood's Therapeutics, which for 25 years has been a standard work, appears in the present edition very much altered in appearance and in the arrangement of the subject matter. The authors have done a great service to the student by endeavoring to present the articles according to a uniform plan, and by putting the less important portions in smaller type. The text also has been made more readable by removing the references to the end of each chapter. The doses are given according to the metric system and in apothecaries' weights and measures. Of course there are new articles on the newer drugs. Moreover, by judicious excision, conciseness of statement, and rearrangement of the text it has been possible to reduce the size of the volume. There can be no question that the changes have improved the book, good as it has always been, and that it will continue to be a trustworthy guide to therapeutics. [H.B.A.]

The Year-Book of the Nose, Throat, and Ear. The Nose and Throat edited by G. P. HEAD, M.D. The Ear edited by ALBERT H. ANDREWS, M.D. Chicago: The Year-Book Publishers.

This volume is one that should meet the approval and encouragement of those working in the specialty indicated by its title. It comprises a resumé of the more recent articles on the subjects with which it purports to deal, and contains a large amount of information of value both to the specialist and to the general practitioner. In its preparation the editors have culled from over three hundred periodicals and reports and they have succeeded in giving a very fair resumé of the year's literature. No attempt is made to argue pro or con on the various articles abstracted, and when authorities differ equal credit is given to all. There is a good working index of twenty pages.

The book bears much evidence of either haste in preparation or carelessness in editing. It is far from being an up-to-date specimen of the printer's and bookbinder's art and there is not shown the care in systematizing the various subtitles that there should be. Some of the English, particularly in translated articles, is not as smooth and accurate as one has a right to expect. There is no excuse for such a sentence as "Recurrence in five months, which was removed" (page 174), or "The patient could swallow good, . . ." (pages 175-176). It is to be hoped that in future editions these more glaring faults will be eradicated and also that there will be added a table of contents, almost a necessity in a book of this character. [D.B.K.]

Handatlas der Anatomie des Menschen. Bearbeitet von WERNER SPALTEHOLZ mit Unterstützung von WILHELM HIS. 3te Auflage. Leipzig: 1901.

The favorable reception accorded the first volume of Spalteholz's admirable "Handatlas" on its first appearance, now something over three years ago, was by no means limited to Germany, and its excellence was promptly appreciated by American teachers of anatomy. The subsequent issue of the second and the first part of the third volume strengthened this estimate and widely extended the circles in which the work has become a favorite. The purpose of the editor is to cover in about 800 drawings the most important parts of descriptive anatomy; to this end a large number of original drawings have been made from special dissections and preparations, the illustrations of the "Handatlas" representing a selection of those which seemed most instructive and helpful to the student.

The first 200 illustrations of Vol. I, representing the bones, are, taken as a whole, the least satisfactory; not from lack of faithful or capable drawing, but rather from the unsuitableness of the half-tone process to preserve the rugged vigor of line essential in conveying a true impression of bony masses. In addition to lack of spirit, the pictures of the bones, in not a few cases, are marred by unnecessarily intense shadows which add nothing to plasticity and certainly mask details. The areas of muscular attachment are very clearly indicated in color on supplementary outline sketches of the more important bones. An excellent feature is the representation of the smaller skull bones *in situ*, the surrounding osseous parts in relation being indicated in outline.

The illustrations of the joints are especially good, unusual clearness being imparted to the ligaments by the delicate contrast-tint laid over the bones. While, probably, the student may be disappointed in some instances in failing to find the ligaments on his subject presenting the sharply defined forms that the drawings portray, he will have, nevertheless, before him a most clear and comprehensive guide to their study.

Vol. II, including the muscles, the heart, and the blood-vessels, is very satisfactory by reason not only of the attractive and artistic drawings, but also of the excellent judgment with which the dissections have been made, and the views selected to illustrate the parts under consideration. The representations of the arteries are particularly good; those of the veins are somewhat less successful, since they are often marred by unwarranted depth of shadows. An interesting section across the cavernous sinus shows the artery about midway between the lateral and mesial walls of the venous space, the sixth nerve lying in close relation to the artery below, with the ophthalmic division of the fifth, within the lateral wall, extending considerably below the level of the sixth nerve.

It is, however, to Vol. III, devoted to the thoracic and abdominal viscera, that we turn with greatest interest, since the close association of the author with Prof. His, whose work has advanced so materially our appreciation of the true form and relations of the organs, naturally suggests the exercise of unusual critical judgment in the preparation of this part of the subject. Nor have we reason for disappointment, since the drawings, with very few exceptions, are excellent, interesting, and well chosen. They faithfully represent the digestive, respiratory, and genitourinary organs as these appear after careful hardening *in situ*, by which their true form and relations are preserved with, at least, a fair degree of accuracy. That viscera so treated should appear very different from the representations accepted without challenge before the missionary work of the His models is to be expected; that anatomists should have failed so long to appreciate what now is so evident seems incredible. Another valuable feature is the reproduction of the semi-microscopical appearances, as seen under the hand lens, as those of the mucous membrane of the various parts of the digestive tube. Such pictures are most instructive and emphasize the close relations between the gross appearances and the histological details.

The text accompanying the illustrations is not only descriptive of the particular drawing under consideration, but includes the salient points in the anatomy of the parts represented, so that it is, in many cases, an acceptable epitome. The terminology is that of the B N A.—*Nomina Anatomica*—adopted by the Anatomische Gesellschaft at its meeting at Basel in 1895, now generally followed in all recent German works. In this connection it may be of interest to note that W. Krause, with the collaboration of Professors His and Waldeyer, has undertaken a systematic text, based on C. Krause's "Handbuch der Anatomie," especially intended for use with Spalteholz's "Handatlas;" an additional and broader purpose was the demonstration of the advantages of the new nomenclature by putting it to consistent use in a brief although systematic textbook. Reinke is accomplishing a similar object in the text which he is preparing to be used with the recent atlas edited by Toldt. The appearance of the English translation of Spalteholz's Handatlas, by Professor Barker, has brought the B N A terminology to our American students in such an attractive form that its advantages, with slight encouragement on the part of teachers, cannot fail to be appreciated.

In its full classical form, as seen in Krause's text, it is

doubtful whether the B N A will make marked headway in America and England, since the often apparently formidable and truly cumbersome array of words appeals neither to student nor teacher seeking the most convenient and concise mode of expression. Neither, as a matter of fact, does the German student often resort to the Latin terms when his native language is so rich in simpler, and often most expressive, synonyms. As is well known, for a number of years the efforts of the Association of American Anatomists have been directed towards the simplification of anatomical terminology by the pruning of all superfluous words; this worthy desideratum, however, it seems to us, is not incompatible with profiting by the many desirable features of the new terminology. Notwithstanding the truism, "Names but stand for things," there is every reason for preferring terms that shall be consistent and logical and, as far as possible, universally used. That the terminology at present followed in our anatomical textbooks only imperfectly meets such requirements few will deny. Careful study of the B N A shows that when shorn of their somewhat formidable appearance by being Anglicized, the terms in the great majority of cases correspond closely with those usually employed by our own students; that in those cases where more radical differences do exist, the newer terms, in the Anglicized form, might be adopted with profit and great gain in accuracy. One important advantage of the B N A is the substitution of terms indicating the location and relations of parts for those embodying the surnames of investigators. The reaction against this growing evil—and none have been greater offenders in this respect than our Teutonic colleagues—is most timely. While some may be loath to abandon such a time-honored friend as Poupart's ligament in favor of *inguinal ligament*, there is little doubt as to which best expresses the general position of the structure. Association suggests an example of the greater consistency of the newer terminology in the case of the bloodvessels and closely related nerves of the thigh. While we have abandoned the name "crural" as applied to the femoral artery and vein, it is still retained in connection with the anterior crural nerve and the crural branch of the genitocrural nerve. These nerves according to the B N A consistently become the femoral nerve and the femoral branch of the genitofemoral.

This digression is offered in no sense as a defense of the new terminology, which, although it has defects as well as merits, is established on a lasting foundation. It has been rather with the purpose of suggesting to those of our readers who are interested in anatomy and surgery the desirability of acquainting themselves with the undoubted advantages to be derived from the adoption, in a modified form, of many terms of the B N A which will add to the uniformity and accuracy of our anatomical nomenclature.

The last part of Spalteholz, including the nervous system and the organs of special sense, is yet to appear. The beauty and clearness of the work, as far as published, warrant the anticipations of a most interesting and instructive fasciculus when the remaining section is issued. While the German student is to be congratulated on possessing so admirable an atlas, the completion of Dr. Barker's translation of the book will introduce, before long, into our own dissecting rooms a guide which will surely become a favorite. [G.A.P.]

Uterine Fibromyoma.—Dr. Kiewsky (*Gazeta Lekarska*, November and December, 1900) employed intraspinal cocaine (2% solution) in eleven cases. The ages of the patients varied from 18 to 60. Only in one case of uterine fibromyoma did the method result in failure, in spite of an injection of 1.5 cc. In all others anesthesia was produced in from 4 to 8 minutes and lasted from 1 to 3½ hours. In three cases no untoward effects whatever were observed; in the others vomiting and frequency of the pulse were the only unpleasant complications. [A.R.]

A New Cause of Intestinal Obstruction.—Dr. Krawtshenko calls attention in the *Medical Chronicle of the Government of Cherson* to the frequent attacks of intestinal occlusions observed among peasants, owing to their habit of swallowing shells and seeds of fruits. He cites four cases. In two the large intestine was occluded by grape seeds, while in the other watermelon seeds formed the offending cause. [A.R.]

Correspondence.

THE USE OF NITROGLYCERIN IN AFFECTIONS OF THE NEWBORN.

By SAMUEL WOLFE, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN the publication of my paper on "The Causes and Treatment of Urgent and Serious Condition of the Newborn," I appear to advise the use of doses of $\frac{1}{2000}$ of a drop of 10% solution of nitroglycerin. My intention was to advocate $\frac{1}{20}$ of a drop of 1% solution. The error most probably occurred in the original manuscript, and was overlooked in the proof-reading. If you will publish this in correction, I shall appreciate the favor.

THE CASE OF GENERAL CRAWFORD, U. S. A., SIMILAR TO THE CASE OF GENERAL WOOD.

By G. TOTTEN McMASTER, M.D.,
of New Haven, Conn.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN your issue of February 23, 1901, page 358, second column right, you say under the section "A Doctor a Major General," "This is noteworthy because the appointment is in the line," further "it is unprecedented so far as we can recall."

Now this is wrong. One of the best officers of the U. S. Regular Service during the Civil War was Brevet Major-General S. W. Crawford, U. S. Army, who was a surgeon.

Assistant Surgeon S. W. Crawford was appointed from Pennsylvania. For gallant services at the bombardment of Fort Sumter he was raised to Major of the 13th U. S. Infantry (line), and served under Major-General Rosecrans in the West Virginia campaign. He served upon his staff as Inspector-General of the Department until Floyd retreated and the campaign closed with success to the United States.

S. W. Crawford (major) was one of the two officers named by General Rosecrans in response to a request from Washington for promotion to the rank of Brigadier-General and was assigned to duty in the Army of the Shenandoah. He was present at the second battle of Winchester and commanded the advance to Culpeper, and to Cedar Mountain, where in the attack upon it he lost one-half of his brigade. His corps being incorporated with the Army of the Potomac, he was present at South Mountain, and commanded a division at the battle of Antietam after the death of General Mansfield—his corps commander—and was severely wounded.

He rejoined the army on the march to Gettysburg, having been placed in command of the Third Division of the Fifth Corps (Pennsylvania Reserves), participating in the battle upon the left of the line at the Round Top.

Upon the expiration of the term of service in this organization he was placed in command of the regiments of the old (reliable) First Corps, then incorporated with the Fifth as the Third Division of that corps.

This division he commanded through the Rapidan campaign, from Bethesda Church through the siege of Petersburg, the battle of Five Forks and the surrender of Lee's army at Appomattox.

For gallant and meritorious services at the battle of Gettysburg he was breveted Colonel in the regular army; Briga-

dier General for gallant and meritorious service at the battle of Five Forks, Major-General of Volunteers for conspicuous gallantry in the battles of the Wilderness, Spotsylvania Court House, Jericho Mills, Bethesda Church, Petersburg and Globe Tavern (Weldon Railroad) and for faithful service in the campaign; Major-General in the regular army for gallant and meritorious service in the field during the war.

He became Colonel of the 16th U. S. Infantry in 1869, and upon the reduction of the army, which immediately followed, he was transferred to the 2d Reg. U. S. Infantry, and was on duty at Huntsville, Ala., under the Reconstruction Act, for 3 years.

His disability increasing, he made application for retirement, when he by a special enactment was retired Brigadier-General U. S. A., February 19, 1873.

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA.

Opening of New Building.—The new building at the State Hospital for the Insane at Harrisburg, Pa., has been opened with an accommodation for 300 patients.

St. Joseph's Hospital.—Drs. Randle C. Rosenberger and Alfred Hand, Jr., have been appointed pathologists to St. Joseph's Hospital, each to serve 6 months yearly.

Tetanus Following Vaccination.—A man in Harrisburg recently died from tetanus, which it is said was caused by vaccination. After he was vaccinated the arm became very much swollen and shortly thereafter tetanus occurred.

Philadelphia Academy of Medicine.—A meeting and dinner of the Philadelphia members and those of neighboring localities were held at the Stratford Hotel, March 16, 1901. The object of the meeting was to promote the local interest in the association, and to enlarge the local membership.

Proceeds of Charity Ball.—A balance of \$11,200 left after the payment of all expenses connected with the twenty-first annual Charity Ball will be equally distributed among the hospitals of the University of Pennsylvania, the Jefferson Maternity, the Philadelphia Orthopaedic Hospital and Infirmary for Nervous Diseases and the Samaritan Hospital.

A Private Hospital.—Ground has been broken at the corner of North Second and Hamilton streets for a private hospital which is being built by Dr. E. L. Shupe, of Green and Hamilton Streets, this city. The new hospital will be 44 feet front on Second street and extend back 68 feet, will be 3 stories high and will have accommodations for the treatment of from 30 to 40 patients.

Wills' Hospital Ophthalmic Society.—At the suggestion of DR. CHARLES A. OLIVER, the surgeons and assistant-surgeons of Wills' Hospital, met on the evening of February 26, 1901, and formed a society for the presentation and discussion of ophthalmic cases. It was decided to admit to membership the surgical staff and all the clinical assistants. Meetings will be held at 8.15 P. M. in the Hospital building on the second and fourth Mondays of each month. They will be open to physicians who may be invited by members.

Philadelphia Academy of Surgery.—At the meeting of the Philadelphia Academy of Surgery to be held April 1, Doctor John A. Wyeth of New York will read a paper entitled "Amputation at the Hip Joint for Sarcoma; the Tendency to Recurrence." The meeting will be held at the Hall of the College of Physicians, 13th and Locust streets, and any of the members of the medical profession who will be interested in the subject are invited.

Death of Dr. Given.—Dr. S. A. Mercer Given, superintendent of the Burn Brae Sanitarium for Mental and Nervous Diseases, near Clifton Heights, in Delaware County, Pa., died

recently in diabetic coma. Dr. Given had been associated with the late Dr. J. Willoughby Phillips, and succeeded his father, the late Dr. Robert A. Given, in charge of the Burn Brae Sanitarium. He was born in Carlisle in 1860, and graduated from the University of Pennsylvania in 1887. His father, the elder Dr. Given, founded the Sanitarium many years ago, and was widely known in the United States for the success with which he managed this useful institution. The son succeeded to many of his father's admirable personal qualities, and his death, at the early age of 41, will be greatly regretted by all who knew him. His brother-in-law, Dr. Phillips, died only recently.

A Century of Medicine in America.—In an address at Houston Hall on March 15, before the John B. Deaver Surgical Society of the University, Professor James C. Wilson, of Jefferson College, spoke of "A Century of Medicine in America," and told of the great work accomplished by the leaders in that science for its development to a high position. The address was remarkable for its literary treatment of a scientific subject. Though the past century was conspicuous for advance in many lines of thought, he said, medicine probably accomplished greater progress than any other science. The New World is now in a position to repay the Old for many points of advance granted in former years, and is in many respects a leader. America's great surgeons and physicians of the last century were compared favorably with the great names of the Eastern Continent. In a historical sketch of the American Medical Association, Dr. Wilson exhorted his hearers to strive for membership in it, as one of the greatest of assistances to a young practitioner.

Vital Statistics of Philadelphia for the week ended March 16, 1901:

Total mortality	CASES.	DEATHS.
Inflammation of appendix 6, bladder 4, brain 14, bronchi 16, heart 1, kidneys 21, larynx 3, liver 1, lungs 72, pericardium 1, peritoneum 5, pleura 5, stomach and bowels 16, spine 2		167
Inanition 15, marasmus 15, debility 9		39
Tuberculosis of lungs		83
Apoplexy 19, paralysis 15		34
Heart—disease of 27, fatty degeneration of 1, neuralgia of 1		29
Uremia 15, diabetes 3, Bright's disease 7		25
Carcinoma of breast 1, stomach 4, uterus 2, jaw 1, liver 1, rectum 1		10
Convulsions 15, puerperal convulsions 1		16
Diphtheria	33	6
Brain—congestion of 1, disease of 1, softening of 5		7
Typhoid fever	28	3
Old age		11
Cyanosis		3
Scarlet fever	114	9
Influenza 12, abscess of liver 1, aneurysm of aorta 1, alcoholism 2, asthma 2, anemia 1, atheroma 2, burns and scalds 2, casualties 11, congestion of lungs 5, childbirth 1, cirrhosis of liver 4, membranous croup 3, diarrhoea 1, drowned 2, extrauterine pregnancy 1, erysipelas 5, catarrhal fever 1, gangrene of leg 2, homicide 1, hemorrhage from bowels 1, hemorrhage from uterus 1, obstruction of bowels 2, edema of lungs 1, creosote poisoning 1, purpura hemorrhagica 1, pyemia 2, rheumatism 1, sarcoma of stomach 1, sclerosis of spine 1, septicemia 4, suicide 2, teething 3, ulceration of stomach 1, ulceration of foot 1, whooping-cough 2		85

Pediatric Society.—The regular monthly meeting was held March 12, with the president, Dr. T. S. WESTCOTT, in the chair.

DR. J. A. SCOTT read a paper upon **intestinal sand**. The literature of this comparatively rare pathological condition was reviewed and three cases reported. The first case was a woman of 40. The feces contained small regular sand-like bodies which were partially crystalline and somewhat resembled uric acid. There was also some resemblance to bile but no cholesterin was found. It was thought that the appearance of these bodies bore some relation to fruit eaten by the patient. The theory of fruit formation was not borne out by the second case, however, which occurred in a child of 3½ years. The child had periodical attacks of catarrh of the duodenum and ileum and for three or four days after

these attacks the stools would contain fine, reddish, sandlike particles. In the third case what is commonly termed biliary sand was found. Dr. Scott believes that a careful examination of the stools of persons having gastrointestinal or liver disease will finally show the origin of these materials. The pathology is supposed to be practically the same as that of gallstones or urinary calculi.

DR. GEO. MCCLELLAN read an instructive paper on the **Anatomy of childhood**, and afterward illustrated his remarks by stereopticon views. Dr. McClellan spoke of the modifications which occur in the anatomy from birth to puberty. The most important periods in the infant are from birth to the seventh month, and from the seventh month to the end of the second year. In childhood the important changes are confined to the periods between the second and seventh years, and from the seventh year to puberty. Special stress was laid upon the differences in the abdominal contents as found in children and adults. It is a mistake to suppose that the intestines in a child are merely the reproduction in miniature of the arrangement found in the adult. The colon is differently placed, and the sigmoid flexure especially is totally unlike that found in older individuals. The stereopticon views illustrated graphically the relations of the thoracic and abdominal organs.

Pathological Society.—The first scientific business at the meeting of March 14 was an address by DR. JOSEPH MCFARLAND, whose subject was **Some remarks on snake-venom**. A brief review of the researches into the nature of venom and immunizing serums was given, the work of Calmette being dwelt upon particularly. Dr. McFarland then gave the results of his experiments upon 3 horses with cobra and rattlesnake venoms. Heated venom was first used, then unheated venom subcutaneously, and finally, unheated venom was injected into a vein. One horse died from local symptoms, a slough being caused. The tests made with the serum showed that it yielded the best results when large doses of venom were used intravenously. It seems proven that it is impossible to immunize against the local effects of the globulins of venom, but with the peptones it is possible. The possibility of the interchange of serums was also proven. It was not proven that antivenene will protect against the globulins of venom. DR. PACKARD asked if the effect on the heart produced by the venom was such as to justify the popular belief that whisky is a valuable antidote in cases of snake bite. DR. MCFARLAND said that death generally was due to paralysis of the respiratory centers. He also stated that it was safe to say that whisky did more harm than good in cases of rattlesnake bites. These cases are not often fatal in this country under any circumstances, not more than 5% of them proving fatal. Whisky is not a physiological antidote, strychnin better fulfilling the indications. The treatment of snake bite as determined by Calmette is to ligate the part, suck, or draw out the poison, inject chloride of lime solution, 4 drops in each of at least 10 different places near the wound, give strychnin and other stimulants as needed.

DR. DAVID ELSALL read a paper on **The carbohydrates of the urine in diabetes insipidus**. The case studied was a man of 27 who was brought to the hospital in the early stages of typhoid fever. Marked polyuria was proved to be due to diabetes insipidus. The benzo esters of the urine were estimated daily for 2 weeks. There was no increase in the unfermentable carbohydrates. Experiments were then made to determine if the amount of the benzo-esters was caused by diuresis itself. To this end the liquids ingested were reduced until only 68% of the usual amount of urine was secreted. The benzo esters then fell to 62% of their former quantity, thus showing a causative relation. The amount of urinary nitrogen also fluctuated fairly regularly with the benzo esters. The influence of water drinking on the nitrogen of the urine was then studied, the nitrogen being reduced when the water was reduced in quantity. An important conclusion reached is that diet plays the largest part in determining the excretion of carbohydrates.

DR. W. M. L. COPLIN spoke on: 1. **A convenient method of staining a number of sections on one slide**. Four or more sections are mounted on one slide and stained. When counterstaining, one or two of the sections are immersed in one stain, washed, and then the slide reversed and other stains used. In this way each of the sec-

tions are stained by a different method. Care must be taken to wash the slide with alcohol before counterstaining to prevent the stain spreading to the next section. 2. **A modification of the staining methods of Claudius and Van Gieson.** The former method is employed first and Van Gieson's used as a counterstain.

County Medical Society.—The meeting of March 13 was devoted to the consideration of obstetrical topics.

DR. WALTER L. PYLE read a paper on **Postpartum metastatic panophthalmitis with a clinical and pathological study of a case.** This condition is rare since the days of asepsis. It usually comes on from 5 to 15 days after labor, loss of vision often being the first symptom. Enucleation during the activity of the process is not without danger of meningitis and should be deferred. The case reported had developed 10 days after forceps delivery of a woman who had been in labor 56 hours. Rupture had taken place before enucleation was done, a notable point being that it was so far posterior that the front of the eye was left intact.

DR. RICHARD C. NORRIS read a paper entitled **Remarks on the obstetrical forceps employed by the general practitioner.** The technic of forceps deliveries was first considered. Forceps should be boiled in water for at least 10 minutes. The toilet of the patient should be preparation as for a surgical operation. The vagina should not be douched unless there is a known virulent discharge. The operator's hands should be thoroughly disinfected and then covered by rubber gloves. The special topic of the paper was **the management of arrested posterior positions of the vertex.** An accurate diagnosis is the first step, insufficient flexion of the head being the most usual cause of delay. When the head is above the brim of the pelvis one of four procedures is to be chosen: 1. External manipulation, with posture, etc. 2. Internal manipulation, with posture, etc. 3. The application of forceps. 4. Podalic version. In the hands of the general obstetric practitioner podalic version will, as a working rule, give the best results. Forceps must be used in some cases. In cases where the occiput is arrested in front of the sacrum, Dr. Norris has during the past 3 years used forceps as rotators with satisfactory results. This manipulation has been done repeatedly without producing extensive lacerations of the soft parts and with no greater danger to the child than is incurred in other procedures. Reversed forceps applications should not be made even by skilled operators. Rotation by forceps has been condemned very generally, but three years' use has proven its practicability. Dr. Norris uses the Tucker solid blade instrument for this purpose. The handles are deflected toward the side enough to keep the tips of the blades always in the median line of the pelvis. Rotation and traction are used until the R. O. A. position is reached. The forceps are then unlocked and readjusted if necessary. In cases where the head is low down the solid blades are applied to the sides of the head and gradual rotation applied, taking care to keep the head well flexed. The danger in these cases is that the trunk will not rotate. The head must be held after rotation until several expulsive efforts have been made and the trunk rotated. These manipulations were demonstrated on a manikin.

DR. CHAS. P. NOBLE presented a paper on **General considerations of the treatment of placenta previa.** The three dangers of placenta previa are sudden profuse hemorrhage, moderate loss of blood long-continued, and infection. The induction of premature labor is the most important single step in the treatment. Prior to the seventh month of gestation there is but little danger to the mother and viability of the child should be waited for unless in special cases. Bipolar version is of great value in cases of severe hemorrhage. A tampon is to be used only as a temporary expedient while further preparations are being made or assistance summoned. The most rigid asepsis should be used, rubber gloves being especially commended.

DR. GEO. M. BOYD, presented a paper on **Indications for cesarean section in placenta previa.** Placenta previa at present seems to be more frequent than during the past, judging from the statistics of some of the older writers. Of the 2,887 deliveries at the Philadelphia Lying-in Charity there has been 1 placenta previa to every 107 cases. This large proportion may be due to the fact that this institution treats a great many emergency cases. Dr. Boyd places the

maternal mortality at from 10 to 12%. The fetal mortality at the Lying-in Charity has been 81.5%. Any measure which will decrease this high fetal mortality without increasing the danger to the mother is justifiable. Cesarean section will lower fetal mortality and at the same time check hemorrhage from the mother. If hemorrhage comes on before the period of viability, forceps delivery or version may suffice; after viability cesarean section is indicated.

The discussion on the papers of Drs. Norris, Noble, and Boyd was opened by DR. BARTON COOKE HIRST. Dr. Hirst considers it rather unfortunate to exaggerate the dangers of occiput posterior presentations. The general practitioner has a dread of this condition which is unfounded. It occurs in but 25% of all cases, and rotation fails finally to occur in only 4%. Dr. Hirst does not agree with the principle of securing rotation by forceps. He would rather deliver the child by forceps with injury to the soft parts than to rotate by them first. It is possible for the head to rotate without the trunk and not injure the child, but the injury produced by this torsion of the neck has proved fatal in some cases. Regarding placenta previa, Dr. Hirst has met with 24 cases with no fatalities to the mothers. The percentage of mortalities, as given by previous speakers, seem too high. Any one who attends enough cases to be called a specialist should look for a mortality in mothers of less than 1%, and the infant mortality should be under 50%. Cesarean section on account of the infant mortality alone is not justifiable, and he would not at present consider it as a treatment for placenta previa, because it increases the risk to the mother. DR. REYNOLDS WILSON said that forceps blades as now made allow motility of the child's head within their grasp, hence it is immaterial whether they are applied to the sides of the head or the sides of the pelvis. The rotation of the head in occiput posterior presentations by high application of the forceps is not a safe procedure in every instance. The injury to the mother is perhaps greater than to the child. Clinically, placenta previa are of 2 kinds: 1. Those seen early in pregnancy in which the management is fairly easy. 2. Those seen as emergency cases where a total placenta previa has been bleeding for perhaps a week. The majority of the latter are fatal. Full surgical procedure seems dangerous. In these cases the shock of the delivery of the child is a cause of death as well as the hemorrhage. In such a case if the patient was not in too serious a condition, Dr. Wilson would not attempt to separate the placenta, but would penetrate it, do version and use the child as a tampon. When this is accomplished it is advisable to give ergot. Dr. NORRIS stated that his remarks did not apply to cases of occiput posterior that finally rotated, but to arrested cases where something had to be done. The two dangers of forceps rotation are failure of the trunk to rotate and laceration of the soft parts, but the procedure can be successfully accomplished. He does not commend cesarean section for placenta previa. In cases of total or nearly total placenta previa use the tampon only as a temporary expedient, but do not leave the woman until she has been delivered. The statistics of specialists regarding cesarean section have a bad influence on general practitioners. The subject was further discussed by Drs. PRICE, FISHER, COLES, NOBLE, and BOYD.

Wills' Hospital Ophthalmic Society.—Meeting was held March 11, 1901. Dr. S. D. Risley in the chair.

DR. FRANK FISHER presented a case of sympathetic ophthalmitis coming on after a panophthalmitis which had followed a cataract extraction, the patient being 64 years of age. He laid especial stress on the age at which the ophthalmitis had developed and the long period of time elapsing between the condition and the cataract extraction. DR. WILLIAM ZENTMAYER inquired whether it is not rare for the disease to evidence itself in cases in which there is panophthalmitis. In answer to DR. JOHN T. KARLL's question whether the fundus of the sympathizing eye had been examined, Dr. Fisher stated that when he saw the case the eyeground had become invisible. DR. RISLEY asked whether subconjunctival injections of solutions of chloride of sodium had ever been tried by any of the members of the staff. DR. WALTER L. PYLE believed that the occurrence of sympathetic inflammation after panophthalmitis depended upon the amount of destruction of the globe. He believed that if there was decided scleral rupture and escape of most of intraocular contents, sympathetic ophthalmitis was not likely to follow. DR.

CHARLES A. OLIVER had found that all attempts to do useful iridectomy in such cases were futile, the iris-tissue being brittle and friable, while any obtained good results are rapidly lost. He had been successful in several instances by either the Critchett-Story operation or Tyrrell's method of drilling. He had never employed subconjunctival injections to any advantage, nor as yet had made use of large doses of the alkalies, but thought if lymph-formation and circulation are good, the former method might be of assistance.

DR. GEORGE C. HARLAN presented a case of false maculae. The patient, a white man of 23 years of age, whose family and personal histories were negative, had squinted since childhood. He could use either eye. On February 23, 1900, he was admitted to the hospital with an esotropia of 40° preferably fixing with the left eye. A tenotomy of the right internal rectus muscle with an advancement of the corresponding external rectus was done, leaving a residual squint of about 10°. Two weeks later similar operations were performed on the left eye with the result of an overcorrection of 10°. On January 23 of this year, the perimeter showed 10° of esotropia. Maddox rod gave 20° of crossed diplopia. At this time a tenotomy of the right external rectus muscle was done allowing both eyes to fix centrally, but the crossed diplopia remained the same. One week later it was found that the esotropia of 10° still persisted. There was not any monocular polyopia. During fixation with both eyes a crossed diplopia of between 8° and 16° with a hypophoria of one-half to two degrees could be determined. DR. ZENTMAYER made mention of a case of divergent squint with homonymous diplopia occurring in a bright student. DR. RISLEY stated that it was not infrequent to find diplopia after the correction of a divergent squint. He reported a case of cataract extraction on an amblyopic convergent eye in which vision after the operation equalled six twelfths of normal. A later operation upon the fellow previously fixing eye in which vision was brought to more nearly normal, resulted in the patient afterwards having diplopia. DR. FISHER reported a case in which a patient with marked divergence could at will associate the images of the two eyes and dislodge them to his greater comfort. DR. OLIVER gave the details of a case of marked esotropia in early life with want of binocular fusion that through operative interference and want of proper correcting lenses was transferred in early adult life into a case of pronounced though comfortable divergence with good vision in each eye. Recently, for cosmetic purposes, a colleague had so successfully attempted to bring about a parallelism in the two organs that a most troublesome series of diplopias took place, necessitating an operation to restore the originally induced condition of comfortable divergence. DR. BERENS mentioned neuro-muscular memory as being one of the factors in this type of cases and desired to see careful studies from the standpoint of the psychologist made.

DR. BERENS presented a case of successful extraction of a foreign body from the vitreous chamber with a resultant vision of $\frac{5}{6}$ of normal. The patient, a 38-year-old man, came to the hospital on February 12, 1901, with the history of having been struck in the left eye one hour previously by a clipping from a hammer. The external wound, which was vertical and 3 millimeters in size, was situated in the cornea 5 millimeters distance from the nasal limbus. There was a corresponding wound in the iris. The pupil was 4 millimeters in size, and central, and the iris reacted well. Under atropin the pupil enlarged to 8 millimeters. There were numerous vitreous opacities anteriorly, and some posteriorly. The details of the eyeground were slightly veiled. Far down and to the inside two semilunar areas, one of which at first showed a suspiciously bright point could be seen. Under Dr. Berens' guidance, the senior residence surgeon enlarged the corneal wound down and in, did an iridectomy, and placed a magnet tip towards the side of the retinal laceration. Three unsuccessful attempts being made in this direction, Dr. Berens took the tip and inserted it twice, the second time down and out, recovering a piece of steel from that locality. Atropin was instilled and a bandage was applied. On the next day there was slight reaction but there was not any pain. Two days later there was a moderate injection. At this time the patient could tell time on a watch at $\frac{1}{2}$ meter's distance. In 8 days' time the eye was quiet, and vision equalled $\frac{5}{6}$ of normal. The eyeground could be distinctly seen. Four days after this, vision had risen to $\frac{5}{6}$ of normal, and the eye was quiet.

DR. OLIVER exhibited a case of double coloboma of the iris, choroid, and optic nerve, with unusually small cornea in a 16 year-old Italian girl. As far as could be ascertained, there was not any history of inheritance, nor were there any other signs of congenital malformation present. The colobomata were in their usual positions downward and slightly inwards, those of the right eye being the larger. The characteristic curvilinear extension of the retinal vessels along the borders of the colobomatous areas could be plainly seen. The surfaces of the fundus colobomata, which were on a much deeper level than the rest of the eyegrounds, were quite ectatic in places. Refraction in the uninvolved macular regions was myopic and slightly astigmatic. Corrected vision equalled about two-thirds of normal. The visual fields showed defects corresponding with the fundus abnormalities. Both optic nerve heads were considerably enlarged. The retina in the colobomatous areas were visible as thin, almost transparent membranes over and in which a few small vessels could be traced. The case was particularly interesting in the fact that in spite of the apparent microphthalmus, the eyeballs were enormously lengthened in their anteroposterior diameters, giving high degrees of myopic refraction. Dr. Oliver also showed a patient from whom a chip of iron had been spontaneously extruded from the eyeball two years after its entrance into the crystalline lens through the cornea and the iris. No reaction followed the expulsion of the foreign body. The lens itself had been studded with brilliant cholesterine crystals for more than a year's time.

DR. BERENS presented a case showing the recent effects of a plastic operation for symblepharon in which the conjunctiva of the upper lid had been adherent to the cornea over more than two-thirds of its surface, entire freedom of motion being restored to the globe.

DR. OLIVER gave a brief account of a case of interstitial keratitis occurring in the left eye of a 24 year-old man, suffering from other stigmata of hereditary syphilis. He had treated and cured the patient's right eye for a similar attack of keratitis some six months previously. The point of interest in the case consisted in the fact that at the time of the patient's second admission to the hospital, some three weeks previously, the senior resident surgeon, Dr. Van Epps, discovered a sloughing chancreoid involving almost the entire foreskin of the patient's penis, necessitating excision of the sloughing part of the organ.

NEW JERSEY.

Appointed Railroad Surgeon.—Dr. Francis W. Bennett has been appointed surgeon and physician to the Pennsylvania Railroad Company, at Atlantic City, N. J.

DELAWARE.

Resignation.—Dr. Jean M. Wilson, pathologist to the Delaware Hospital for the Insane, has sent in his resignation.

Varicoid.—An epidemic is raging in the lower part of Delaware, in Dover and vicinity. Dr. Knowls, of Dover, is among the victims. The epidemic is mild, the disease lasting only 3 or 4 days.

Licensing Without Examination.—The bill providing for licensing without an examination graduates from the University of Pennsylvania and other reputable institutions was killed by the general assembly of Delaware.

Delaware State Hospital.—The Legislature passed a bill appropriating \$125,000 to the Delaware State Hospital for the Insane, at Farnhurst; also a bill increasing the appropriation for the State Pathological and Bacteriological Laboratory, located at Delaware College, Newark, to \$2,500.

NEW YORK.

Appointment.—Dr. William Browning has been appointed consulting neurologist to the Long Island State Hospital at Flatbush.

New Hospital.—A new brick and brownstone hospital building, five stories in height, will be erected in One Hundred and Thirty-sixth Street, near Amsterdam Avenue, for

the Hebrew Benevolent and Orphan Asylum Society, at an estimated cost of \$70,000. The new hospital will be used for emergency purposes.

Dr. Delafield will Resign.—Dr. Francis Delafield, one of the leading pathologists in the country, will give up the chair of the practice of medicine in the College of Physicians and Surgeons, on June 1. He asked to be relieved of the professorship some time ago. Dr. Walter Belknap Jones has been appointed lecturer on the practice of medicine.

Female Nurse Appointed.—Secretary Root has appointed Mrs. Dita Hopkins Kinney, of New York City, superintendent of the female nurse corps under the army reorganization act. Mrs. Kinney has been superintendent of the nurses in the Long Island Hospital, at Boston, and has been connected with hospitals in St. Paul, San Francisco and New Mexico. She was selected to be superintendent of the hospital that was proposed to be established at Nagasaki during the Chinese troubles. Recently she has been in charge of the army nurse corps in the War Department.

New York Academy of Medicine—Section on Orthopedic Surgery.—Meeting of February 15, 1901, DR. GEO. R. ELLIOTT, Chairman. The subject of the evening's discussion was a symposium on Clubfoot. DR. H. W. BERG read a paper entitled "The Etiology of Congenital Talipes Equinovarus." He devoted a part of his paper to again calling attention to views elaborated and published by him in 1881. He said it was a fact that talipes equinovarus was a morphological stage in the normal development of the lower extremity of every human fetus. In early fetal life the leg as a whole rotated outwards and this outward rotation was accompanied by an exaggerated varus and later an equinovarus. This outward rotation reached its maximum as soon as the joints were formed. The thighs were flexed upon the body and the legs partially flexed upon the thighs. The wide border of the thigh and the tibial border of the leg pressed against the abdomen of the fetus, the legs crossing each other. All intrauterine pressure was thus brought to bear directly upon the outer border of the thigh and leg. As a result the foot was rotated in and extended (equinovarus). This then was a stage in the normal development of every healthy fetus, and were the extremities to remain in this position all children would be born club-footed. Nature provided against this by an inward rotation of the extremity carrying the leg away from its position against the abdomen of the fetus. The soles of the feet came to lie against the uterine walls and intrauterine pressure was exerted directly upon them producing extreme flexion and outward rotation of the foot—thus was antagonized the varus or equinovarus which had hitherto existed. This inward rotation began about the second month, was to a great extent accomplished by the fourth month, but not complete till the fifth or beginning of the sixth month. Now if this inward rotation, this second rotation stage did not occur or was incomplete the child was born more or less club-footed. The different stages of rotation were illustrated by fetal specimens from the museum of the New York Hospital. Dr. Berg denied that his views were those of Eschricht as some had claimed. He said Eschricht himself had said that talipes equinovarus was a stage in the development of the lower extremities of the human fetus, but Eschricht had not explained how it was produced. There was no embryological data at that time (1851).

DR. J. E. KELLY's paper dealt with the mechanism of the foot and the advantages to be derived from the anatomical study of the factors and treatment of talipes. He called attention to the erroneous idea which persisted as to the existence of a transverse arch in the foot. We said it was impossible, as it had no internal abutment; it bore a greater resemblance to a "flying buttress," the upper and inner extremity of which was supported by the so-called longitudinal arch. In reality it was a semi-dome which, with its fellow foot, constituted a dome upon the apex of which the weight of the body rested. He called attention to the benefits obtained by utilizing the stability of the margins of the semi-dome in walking, especially in those tending to pes planum and talipes valgus. He dwelt on the fact that the factors in the third and fourth degrees of talipes equinus, varus and equinovarus had best be divided into hyperextension, adduction,

torsion, and longitudinal folding, and with the exception of the last, which results from the simple approximation of the internal and external margins of the foot, each of these factors is complex, and may occur in two or more anatomical sites and in different degrees, thus accounting for the infinite variety of talipes. He reviewed the different factors in detail—action of the muscles and resistance of ligaments, and observed as a summary that the factors in hyperextension, or vertical deformity, are the retraction of the heel, luxation downwards and forwards of the astragalus and the plantar flexion at Chopart's articulation. Adduction is due to the curvature in the neck of the astragalus, displacement of the scaphoid and the traction exercised by the severed tendons and muscles on the inner aspect of the foot. The torsion is caused by the rotation of the scaphoid on its anteroposterior axis, the traction of the tibialis anticus on the inner margin. He pointed out that the peculiar facilities of section, resection and dissection were afforded in the two margins of the foot, and indicated the positions from which the different structures could be most easily reached. He said, owing to the direction of fibers of the plantar fascia, it was best to divide it posteriorly near the tubercle of the os calcis, where the flexor dig. brevis, the flexor accessorius and the long plantar ligament might be divided. The division should be obliquely forward and outward, parallel to the ext. plantar vessels and nerves. Should the external septum need special section, it could best be approached from the external margin. He advocated the division of tendons close to their insertion. Owing to the slight importance of toes in ordinary locomotion, he suggested dividing the numerous digital tendons close to the metatarsophalangeal articulation. Owing to his observation on the perfect restoration of ligaments of great mechanical importance, he thought it expedient in subluxation of the astragalus to consider as an alternative to resection, the free division of the lateral and posterior ligaments and the replacement of the bones which should, under the persistent influence of the modelling pressure and adaptive shortening, result in a restoration of the articular functions.

DR. E. D. FISHER, in speaking of the neurological aspect of talipes, said, that the only class of talipes interesting to the neurologist was that class originating from lesions of the brain, spinal cord, or peripheral nervous system. The two main causes of talipes of this class were diseases of the motor tracts of the brain and spinal cord. Another form of talipes was that due to infantile spinal paralysis. Certain definite symptoms differentiate true congenital clubfoot from that of cerebral or spinal origin. In the deformity resulting from central nerve disease were found reflex disturbances, usually exaggerated reflexes associated with spastic conditions of the muscles, and commonly the Babinski symptom—the extension of the toes on irritation. This latter phenomenon associated with exaggeration of the patellar and knee-jerk always pointed to disease of the pyramidal tracts and present whenever there was disease of the lateral tracts; in cerebral hemiplegia in the later stages; in the secondary changes following myelitis; in lateral and multiple sclerosis. In congenital clubfoot, on the contrary, there was no central nerve disease, therefore no disturbances of the ordinary physiological actions of the spinal cord and brain, hence no disturbances of the reflexes. In making a differential diagnosis between the congenital type of clubfoot and clubfoot due to infantile spinal paralysis he said the muscular electrical reaction determined the diagnosis. Referring to treatment, he said of late years interesting experimental work had been done. In cases of spastic paraplegia for a long time neurologists were opposed to operation, but now he recommended section of tendons, and putting patients in a condition to walk. He referred to transplantation of tendons to opposite muscles or muscles of opposed functions, such as transplanting a flexor tendon to an extensor muscle or vice versa. He referred to a boy with central hemiplegia who could not extend his hand. The extensor tendon was transplanted with the result of giving boy a useful hand.

DR. NEWTON M. SHAFFER spoke of the nonoperative treatment of clubfoot. He said he was accustomed to divide his clubfoot patients into three classes: Vertical, antero-posterior, and transverse. By careful study of each case and by making each instrument an individual prescription to fit the given case, he had achieved results which at first appeared impossible. The necessity for operation was getting further

and further away. He said in the first class of cases of ordinary clubfoot, without much deformity, good results could be accomplished by manipulation, massage, electricity, or perhaps some form of walking apparatus. The careful carrying out of nonoperative treatment in these cases should result in cure in a year's time. In the second class, where the deformity is greater, especially in equinovarus, we meet with resistance which may be osseous, or fibrous. Experience here was necessary to determine whether operative or non-operative measures should be adopted. It was difficult to give any positive rule, however; he was inclined to agree with the elder Doctor Sayre and not operate if we could trace our lesion to cerebral source. The rule had exceptions. In the third class—the resistant—usually some form of operative procedure was indicated. This class fell into the hands of the general surgeon. Referring to cutting the tendo Achilles, he said he did not cut when, in taking hold of the foot, he felt the resistance gradually give away.

DR. A. M. PHELPS in speaking of the operative treatment of clubfoot said that in considering when and why to operate nothing had been said regarding age of patient. If a rigid foot occurred in a child two months of age, and that same rigid foot in a child of six years, there was a vast difference. In the two months' old baby the condition could be cured by the mechanical nonoperative treatment; in the older child such a thing was impossible. For that reason he believed all cases should be divided into classes according to age and deformity. In a certain type of talipes in newborn children the human hand was the best instrument, and the deformity could be cured by manipulation before the child was nine years old. In other cases, even after four months, there was great resistance and operation was required the same as at the age of six years. Operations on the soft parts are all that were indicated up to a certain age and to a certain degree. In a child of four months a subcutaneous tenotomy was all that would be required in the majority of cases, but having once commenced to operate the foot must be straightened at the expense of a more extensive operation. At the age of two or three years, instead of applying apparatus for a year or so, he advised subcutaneous tenotomy observing the rule to get the foot straight. Regarding open operation he said frequently surgeons neglected to carry out the necessary after-treatment. He objected to the operations when bone was removed, such as removing the astragalus which caused shortening of the leg; or the removal of a V-shaped portion from the tarsus which shortened the foot. He said he resorted to subcutaneous tenotomy, and if this was not sufficient to allow of straightening the foot, he made an open wound and cut whatever resisted. Occasionally he found it necessary to take a V out of the os calcis; occasionally the deformity was so great that nothing short of amputation was indicated. He advocated thorough operative measures rather than spending years with mechanical appliances and subcutaneous tenotomies.

Dr. Phelps presented a boy, 16 years old, upon whom he had performed the open incision operation four weeks previously. The boy was born with extreme equinovarus of the right foot and had worn various mechanical appliances. He cut the tendons necessary to straighten the foot and pulled it into position.

DR. SAYRE cited a case of his own some years ago in which both feet were deformed. He operated on one, taking out the astragalus. Later, he did not like the condition of the foot and when he came to operate on the other, the worst one, he did not remove the astragalus but divided by subcutaneous incision and wrenched the foot into place, getting a better result than by taking out the astragalus. The patient was a man 26 years old, who was deformed since birth. The question then came up as to whether the foot should be brought to a right angle by means of an operation through the bone of the tarsus or by going above the tarsus. The idea of going through the tarsus was abandoned for the reason that by years of walking in an abnormal position the foot had adjusted itself to a peculiar formation of the facets of articulation of the bone, and it seemed better to allow this confirmation to remain and to cut through above the malleolus, taking out a piece of the tibia and fibula. A wedge of the tibia was therefore removed and the result has enabled the patient to walk very comfortably.

In the discussion, DR. ELLIOTT said he agreed with Dr. Shaffer that in certain forms of congenital clubfoot delayed

muscular growth seemed to call for some cause beyond the mechanical one described by Dr. Berg. Dr. Berg had clearly demonstrated that equinovarus was a stage in the development of every human fetus. He failed to believe that nature so frequently failed in her unfolding process, without some pathological reason, as the great number of clubfeet would indicate. This lack on the part of nature to unfold properly was contrary to her workings throughout the animal and vegetable kingdom. Regarding the treatment of clubfoot he thought Dr. Phelps had struck the keynote to the successful treatment in dwelling upon the advisability of dealing with resistance which could not be overcome by manipulation by operation. Those who had seen many cases of clubfoot in babies could not fail to have noticed that many were easily cured by manipulation while others resisted all manipulative procedures. Any foot left short of the flaccid state was certain to relapse.

DR. BERG said he considered Dr. Shaffer's lateral traction shoe a most admirable device and he thought Dr. Phelps' open incision was also the treatment par excellence for certain cases. In regard to Dr. Sayers' question as to why external rotation of the lower extremity remains and why internal rotation does not occur, he did not think it applied at all. It made no difference why it happened thus; the fact remained just the same. We are satisfied to know what form of arrested development causes hare lip or spina bifida without inquiring why such arrest of development occurs. In his paper he had purposely avoided theory as much as possible.

DR. PHELPS said in regard to the traction shoe that if a muscle was pulled upon for years atrophy was sure to follow and said further that he had observed atrophy so produced in hundreds of cases. On the other hand if you divided a tendon the normal nutrition of the muscle was preserved.

DR. SHAFFER stated that he had kept records of a series of cases that had been stretched as to muscles and he wished to say that Dr. Phelps was entirely mistaken. In his experience the muscles had become stronger by stretching. He wished this remark recorded. He stated that in a long series of cases extending over years of practice he had not once seen atrophy. In regard to Dr. Phelps' statement about "stretching muscles for years" he would like to ask who did such a thing. He also said that he had patients who wore the traction shoe for a short time in the morning in the winter because after it the foot kept warm all day; he did not think that the state of things indicated atrophy.

NEW ENGLAND.

Smallpox at St. Alban's.—Dr. A. H. Barbe, secretary of the State Board of Health, received an official report of 49 cases of smallpox and 4 recent deaths from the disease at St. Alban's. The epidemic has existed for 3 weeks.

CHICAGO AND WESTERN STATES.

Appointment.—Dr. W. D. Zoethout has been appointed laboratory professor of neurology in Rush Medical College, Chicago, Ill.

American Medico-Psychological Association will hold its annual meeting in Milwaukee, Wis., June 11, 12, 13 and 14, 1901.

Indians Dying of Diphtheria.—It is reported that 7 deaths from diphtheria have occurred among the Indians at the Flathead Reservation. The Indians are ignorant of the nature of the affection and consequently intermingle indiscriminately.

Cleveland German Medical Society.—The following officers were elected for the ensuing year: President, Dr. C. Schmitz; vice president, Dr. I. Ballowski; secretary, Dr. M. Kahn; corresponding secretary, Dr. Leo Reich; and treasurer, Dr. I. J. Propper.

Endowment for a Library and Pathological Laboratory.—Dr. William E. Quine gave \$25,000 to endow a library for the College of Physicians and Surgeons of Illinois, and Dr. D. A. K. Steel \$25,000 for the establishment of a pathological laboratory.

Appointment.—Dr. Frederick C. Schaefer has been appointed gynecologist to St. Elizabeth's Hospital, and surgeon in chief to St. Hedwig's Hospital, Chicago.

Death of Dr. James A. Ewing.—Dr. James A. Ewing, treasurer of the St. Louis Hospital Association, St. Louis, died on March 16, at the hospital, aged 33 years. He returned two weeks ago from Las Vegas, N. M., whither he went last September to recuperate.

Medical Practice Bill Passed.—The Senate of Missouri has passed the Hall medicine practice bill, which has been strongly opposed by the Christian Scientists of Missouri since it began its course early in the session. The bill has been signed by the Governor.

Village for Epileptics.—A bill introduced in the House of Representatives of Indiana provides for a village for epileptics, to be erected by the State. The sum of \$40,000 is to be appropriated for the purpose of purchasing a tract of not less than 1,000 acres of land, and not more than \$160,000 for the erection of buildings. No site has yet been selected.

Exposed Himself to Contagion.—A physician of Appleton, Wisconsin, has made himself notorious by visiting smallpox patients, breaking the pustules, and smearing the contents over his face, hands, and clothing, in an attempt to prove that the disease is not contagious. He was caught by the health authorities, confined, and quarantined. There was so much public excitement in Appleton that he came very nearly being mobbed.

Hospital for the Treatment of Incipient Tuberculosis.—A bill has been introduced into the legislature of Wisconsin providing for the establishment of a hospital for the treatment of incipient tuberculosis to be known as the Wisconsin State Sanitarium. The bill provides that "All persons afflicted with incipient pulmonary tuberculosis may be admitted to said hospital after such examination into their condition as is required to be made to determine the condition of persons who are alleged to be insane and for whom admission is sought to the State hospitals or county asylums for the insane. All the provisions of law relating to the examination and commitment of such alleged insane persons, shall, so far as practicable, apply to persons whom it is sought to have committed to the hospital for those afflicted with incipient pulmonary tuberculosis; and all powers conferred upon the judges of the several courts as to such alleged diseased persons, and all duties devolving upon such judges in relation to their examination and commitment shall be exercised in the examination and commitment of persons to said hospital, so far as such powers and duties are applicable.

SOUTHERN STATES.

New Central State Hospital.—The new Central State Hospital at Petersburg, Va., has recently been opened, with accommodations for 160 patients.

Old Dominion Hospital.—This hospital in Richmond connected with the Medical College of Virginia, is about to be enlarged so as to accommodate forty more patients.

Orphans' Home.—An Orphans' Home for physicians' children is being established at Bristol, Tenn. Dr. N. H. Reeve, of that place, is the secretary of the board of trustees.

Legislature on Cocain.—The State Legislature of Georgia, at its last session, passed a law imposing a fine on any dealer guilty of selling cocain except on a prescription of a physician.

Plan Revised for a Municipal Hospital.—Health Commissioner Bosley's ordinance appropriating \$25,000 for the establishment of a municipal hospital for infectious diseases was introduced in both branches of the Baltimore City Council and referred to the Committee on Health.

University College of Medicine Hospital.—This hospital, adjoining the Virginia Hospital of Richmond, is nearly completed. It will have a capacity of some sixty or more patients. Its clinical amphitheater is built on t' e

most approved plans, having all the convenient arrangements for demonstrations, etc.

Death of Dr. George C. Venable.—Dr. George Carrington Venable died at his home in Lynchburg, Va., on March 13, aged 73 years. He was born in Charlotte county and was the only son of Dr. Paul C. Venable and Emily Eaton Carrington. After his graduation in medicine at the University of Pennsylvania in 1847 he practised in his native county and continued there until 10 years ago, when he came to Lynchburg.

Death of Dr. J. W. H. Lovejoy.—Dr. James W. H. Lovejoy, one of the best-known members of the medical fraternity of Washington, died at his residence in Washington, aged 76 years. Dr. Lovejoy was chairman of the executive committee of the Children's Hospital, and also served several terms as president of the Medical Society of the District. He was one of the incorporators of Garfield Hospital, and had been president of the faculty of Georgetown University Medical School. Dr. Lovejoy came from one of the oldest families in the District, and his father and grandfather lived in the house in which he died. At an early age he took up the study of medicine and graduated from Jefferson College in Philadelphia. He practised in Washington for a good many years.

Louisiana State Medical Society.—The following is the list of officers for 1901: President, Dr. F. W. Parham, New Orleans; vice presidents, First Congressional District, Dr. C. J. Landfried, New Orleans; Second Congressional District, Dr. John Callan, New Orleans; Third Congressional District, Dr. C. M. Smith, Franklin; Fourth Congressional District, Dr. T. G. Ford, Shreveport; Fifth Congressional District, Dr. O. M. Patterson, Bastrop; Sixth Congressional District, Dr. R. C. Webb, Rayne; recording secretary, Dr. H. B. Gessner, New Orleans; corresponding secretary, Dr. A. G. Friedrichs, New Orleans; treasurer and librarian, Dr. H. S. Cocram, New Orleans.

SECTIONS.

Surgery.—Dr. E. D. Martin, chairman, New Orleans. Subject for discussion, Treatment of Fractures of the Long Bones of the Upper and Lower Extremities.

Genito-Urinary Surgery.—Dr. Charles Chassoignac, chairman, New Orleans. Subject for discussion, Treatment of Cystitis.

Materia Medica and Therapeutics.—Dr. L. Sexton, chairman, New Orleans. Subject for discussion, Is the Tendency Toward Prescribing Proprietary Medicines Increasing; Its Final Effect upon the Professions of Medicines and Pharmacy.

Ear, Nose and Throat.—Dr. O. Joachim, chairman, New Orleans. Subject for discussion, The Middle Ear Inflammations of Childhood and their Consequences.

Ophthalmology.—Dr. E. A. Robin, chairman, New Orleans. Subject for discussion, When Not to Operate in Anomalies of the Extrinsic Muscles of the Eye.

Dental and Oral Surgery.—Dr. A. G. Friedrichs, chairman, New Orleans. Subject for discussion, The Care of Children's Teeth.

Nervous Diseases.—Dr. P. E. Archinard, chairman, New Orleans. Subject for discussion, Alcohol in Its Relation to Nervous Diseases.

Sanitary Science.—Dr. E. Souchon, New Orleans, chairman. Subject for discussion, The Prevention of the Spread of Contagious Diseases.

Quarantine.—Dr. J. N. Thomas, Port Eads, chairman. Subject for discussion, The Period of Incubation of Yellow Fever.

Dermatology.—Dr. J. N. Roussel, chairman, New Orleans. Subject for discussion, Dandruff.

Practice of Medicine.—Dr. W. Glendower Owen, White Castle, chairman. Subject for discussion, Scarlet Fever.

Medical Jurisprudence.—Dr. C. D. Simmons, Dutchtown, chairman. Subject for discussion, Board of Lunacy, with Especial Reference to the Examination of Patients for Commitment in the Insane Asylum.

Obstetrics and Gynecology.—Dr. E. S. Lewis, New Orleans, chairman. Subject for discussion, Lacerations of the Cervix and their Consequences.

MISCELLANEOUS SUBJECTS.

In the final program it is the object of the committee of arrangements to have these topics called for at any session where the general discussion on any section has been completed, thereby adding to the interest of each session of the Society.

1. Overaction of the Heart from Administration of Hyoscin, by Dr. Parsons, of Minden, La.
2. Thirty cases of Acute Lobar Pneumonia, with 29 Recoveries, by Dr. Edward D. Newell, St. Joseph, La.
3. Otitis Media Neonatorum, by Dr. O. Joachim, New Orleans.
4. Affections of the Nose and Throat as Factors in Diseases of the Bronchi and Lungs, by Dr. W. Scheppegegrell, New Orleans.

CANADA.

Vital Statistics.—Winnipeg's vital statistics for February were: 110 births, 62 male and 48 female; 71 deaths, 40 male and 31 female; marriages, 39.

Held on the Charge of Graveyard Desecration.—The *Canada Lancet* states that a third year medical student in Queen's College, Kingston, was recently arrested at Peterborough for robbing a grave in order to secure a body for dissection. The charge of robbery was withdrawn by the prosecution, as there was nothing in Canadian law governing such an offence, there being no property in a dead body. He is held for trial, however, at the Assizes, in bonds of \$2,000, on the charge of graveyard desecration and offering indignity to the dead. The police magistrate, in giving judgment, held that while Canadian law did not cover this point, English law, which makes it a punishable offence, would probably be applicable in the present instance. Since more ample provision of dissecting material has been made under the Anatomy Act, cases of this kind in Ontario have fortunately been of very rare occurrence.

MISCELLANY.

A Useful Millionaire.—Alexander Graham Bell, the inventor of the telephone, has been serving as a special agent of the Census Bureau in charge of the enumeration of the deaf, dumb, and blind population of the country, and is now preparing his report. Mr. Bell is a millionaire several times over, but is entitled to \$6 a day from the Government while he is employed in this work. In his early life he was an instructor in a deaf and dumb asylum, and a large part of his time is now spent in the investigation of means for promoting the education of deaf-mutes and sightless people.

Obituary.—DR. CHARLES H. BOWEN, at Washington, D. C., on March 12, aged 65 years.—DR. R. R. HALL, at Fayette County, Ky., on March 14, aged 85 years.—DR. E. H. DAVIS, at Plainfield, Conn., on March 15, aged 56 years.—DR. HENRY N. LOVELACE, at Apex, Mo., on March 15, aged 60 years.—DR. HENRY M. SMITH, at Escondido, Cal., on March 16.—DR. S. R. McCLANAHAN, at Culpeper, Va., on March 19, aged 70 years.—DR. J. J. SMITH, at LaCrosse, Wis., on March 16, aged 63 years.—DR. JOHN SARGENT, at Jefferson County, N. Y., aged 87 years.

Changes in the Medical Corps of the U. S. Army, for the week ended March 16, 1901:

Notice.—Candidates for appointment as Dental Surgeons in U. S. Army will be examined in the following named branches:—Anatomy; physiology; histology; physics; chemistry; metallurgy; dental anatomy and physiology; dental materia medica and therapeutics; dental pathology and bacteriology; orthodontia; oral surgery; operative dentistry, theoretical; prosthetic dentistry, theoretical; operative dentistry, practical; prosthetic dentistry, practical. An average of 75% will be required in each subject for theoretical examination, and 85% in the practical examinations.

KNAPP, GUSTAV, hospital steward, a patient in the Army General Hospital, Presidio, will be sent to the Army and Navy General Hospital, Hot Springs.

SKINNER, First Lieutenant IRA A., assistant surgeon, is granted leave of absence for 1 month, with permission to apply for an extension of 1 month.

HALL, HENRY M., acting assistant surgeon, is relieved from temporary duty at the Army General Hospital, Presidio, and will report for temporary duty at Major Lockwood's camp of recruits and casuals on the Presidio reservation, awaiting transportation to the Philippine Islands.

SUMMERALL, W. B., acting assistant surgeon, is granted leave of absence for 1 month, with permission to go beyond the limits of the department of Cuba.

PLUMMER, GEORGE R., acting assistant surgeon, now on duty at Battery No. 5, Havana, Cuba, will proceed to Hamilton Barracks, Matanzas, Cuba, for temporary duty during the absence of Acting Assistant Surgeon W. B. Summerall.

ERCK, PHILIP F., hospital steward, will be granted a furlough for 6 months, by the commanding officer of Fort Monroe, with permission to leave the United States, to take effect about April 10.

MITCHELL, JAMES, acting assistant surgeon, will proceed to his home, Lancaster, Pa., for annulment of contract.

LEHARDY, JULIUS C., acting assistant surgeon, will proceed to his home Savannah, Ga., for annulment of contract.

ATHEY, WILEY L., acting assistant surgeon, will proceed to his home, New York, N. Y., for annulment of contract.

ADAIR, Major GEORGE W., surgeon, is granted leave of absence for 1 month, upon being relieved from duty at Fort Sheridan.

The following named assistant surgeons, U. S. Volunteers, recently appointed, now in San Francisco, Cal., will report to the commanding general, department of California, for transportation to Manila, P. I., where they will report to the commanding general, division of the Philippines, for assignment to duty: Captains ELMER S. TENNEY, and CLARK I. WERTENBAKER.

WILLIAMS, CHARLES F., acting assistant surgeon, will proceed from Yorkville, S. C., to Fort Screven, for temporary duty.

ANDREWS, Captain CHARLES H., assistant surgeon, recently appointed, now at the Presidio, will report for transportation to Manila, P. I., where he will report for assignment to duty.

CHAFFER, First Lieutenant JEROME S., assistant surgeon, recently appointed, will proceed from Dover Plains, N. Y., to Columbus Barracks, for duty.

HICKS, JOHN R., acting assistant surgeon, is granted leave of absence for 21 days, with permission to apply for an extension of 7 days.

BOYCE, NEWTON J., acting assistant surgeon, is relieved from duty on the transport "McClellan," and will proceed from New York City to San Francisco, Cal., and report for assignment to duty with troops en route to the Philippine Islands, where he will report for assignment to duty.

DRIVER, G. S., acting assistant surgeon, is granted leave of absence for 6 days.

LAINE, Major DAMASO T., surgeon, is granted leave of absence for 10 days, on surgeon's certificate.

GORGAS, Major WILLIAM C., surgeon, is granted leave of absence for 14 days, with permission to go beyond the limits of the department of Cuba.

GILHULEY, JOHN J., acting assistant surgeon, is relieved from temporary duty at Fort Columbus and will proceed to Fort Terry, and relieve Acting Assistant Surgeon Arthur I. Boyer.

BOYER, ARTHUR I., acting assistant surgeon, will proceed to Fort Columbus for duty.

PENROSE, Major GEORGE H., surgeon, leave of absence granted February 11 is extended 1 month, on surgeon's certificate.

COX, Captain FREDERICK W., assistant surgeon, recently appointed, will proceed from Vermillion, S. D., to San Francisco, Cal., for transportation to Manila, P. I., where he will report for duty.

CONN, FREDERICK A. W., acting assistant surgeon, is granted leave of absence for 1 month.

WHITNEY, Major WALTER, surgeon, recently appointed, will report at Fort Walla Walla, for duty.

POND, Major ARLINGTON, surgeon, recently appointed, will report at Fort Preble, for duty.

POND, Major ARLINGTON, surgeon, is relieved from duty at Fort Preble to take effect upon the arrival at that post of Acting Assistant Surgeon Ernest W. Fowler, and will then proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.

POND, Major ARLINGTON, surgeon, is granted leave of absence for 14 days, to take effect upon his being relieved from duty at Fort Preble.

DISNEY, Captain FRANK A. E., assistant surgeon, recently appointed, now at San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty.

SHIMER, First Lieutenant IRA A., orders of February 25 relating to him are revoked.

HUTTON, First Lieutenant PAUL C., recently appointed, now in Washington, D. C., will proceed to Fort Thomas, for duty.

FOWLER, ERNEST W., acting assistant surgeon, will proceed from New York City to Fort Preble, for duty, to relieve Major Arlington Pond, surgeon.

Changes in the Medical Corps of the U. S. Navy, for the week ended March 16, 1901:

McCLANAHAN, R. K., assistant surgeon, detached from the "Indiana," and ordered to wait orders for sea duty.

EAKINS, O. M., assistant surgeon, resignation accepted, to take effect from April 15.

MORSE, E. T., pharmacist, detached from the Boston Navy Yard, and ordered to the "Michigan."

HURD, I. N., pharmacist, detached from the "Wabash" and ordered to the Boston Navy Yard.

Changes in the U. S. Marine-Hospital Service, for the week ended March 17, 1901:

BAILHACHE, PRESTON H., surgeon, is relieved from duty at the bureau and directed to Stapleton, N. Y., and assume command of the service, relieving Surgeon G. W. Stoner. March 8.

STONER, G. W., surgeon, upon being relieved by Surgeon Preston H. Bailhache, is to proceed to immigration depot, New York, N. Y., and assume command of the service, relieving Surgeon L. L. Williams. March 8.

CARTER, H. R., surgeon, upon being relieved by Past Assistant Surgeon G. B. Young, is to proceed to Baltimore, Md., and assume command of the service, relieving Passed Assistant Surgeon B. W. Brown. March 8.

GLENNAN, A. H., surgeon, is granted leave of absence for 11 days from March 6. March 8.

WILLIAMS, L. L., surgeon, upon being relieved by Surgeon G. W. Stoner, is to proceed to Washington, D. C., and report at bureau for duty. March 8.

YOUNG, G. B., passed assistant surgeon, upon being relieved by Assistant Surgeon C. H. Lavinder, is to proceed to Louisville, Ky., and assume command of the service, relieving Surgeon H. R. Carter. March 8.

BROWN, B. W., passed assistant surgeon, upon being relieved by Surgeon H. R. Carter, is to proceed to Evansville, Ind., and assume command of the service, relieving Passed Assistant Surgeon J. H. Oakley. March 8.

NYDEGGER, J. A., passed assistant surgeon, is relieved from duty at Chicago, Ill., and directed to assume command of the Cape Charles Quarantine Station, relieving Assistant Surgeon C. W. Wille. March 11.

The official list of changes dated January 17, 1901, is amended so that leave of absence granted Passed Assistant Surgeon Nydegger for 30 days shall read, "leave of absence on account of sickness." March 13.

OAKLEY, J. H., passed assistant surgeon, upon being relieved by Passed Assistant Surgeon B. W. Brown, is to proceed to Cairo, Ill., and assume command of the service, relieving Assistant Surgeon J. M. Holt. March 8.

MATHEWSON, H. S., assistant surgeon, is to proceed to Washington, D. C., for examination for promotion. March 8.

LAVINDER, C. H., assistant surgeon, is to proceed to Delaware Breakwater and assume command of the service, relieving Passed Assistant Surgeon G. B. Young. March 8.

FOSTER, M. H., assistant surgeon, is granted leave of absence for 20 days from April 1. March 11.

KING, W. W., assistant surgeon, is to proceed to San Juan, Porto Rico, for special temporary duty. March 8.

HOLT, J. M., assistant surgeon, upon being relieved by Passed Assistant Surgeon J. H. Oakley, is to report to him for duty. March 11.

TROTTER, F. E., assistant surgeon, is granted leave of absence for 26 days from April 9. March 11.

WILLE, C. W., assistant surgeon, upon being relieved by Passed Assistant Surgeon J. A. Nydegger, is to report to him for duty. March 11.

DUDLEY, D. E., acting assistant surgeon, is relieved from duty at Havana, Cuba, and assigned to duty in the office of the United States Consul at Vera Cruz, Mexico. March 1.

HODGSON, S. H., acting assistant surgeon, is relieved from duty at Vera Cruz, Mexico, and assigned to duty in the office of the United States Consul at Progresso, Mexico. March 1.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended March 16, 1901:

SMALLPOX—UNITED STATES.

foreign News and Notes.

GREAT BRITAIN.

Appointment.—Lord Lister has been appointed Sergeant-Surgeon in Ordinary to His Majesty.

Reelection.—Dr. Parry has been reelected president of the Royal Medical and Chirurgical Society for the ensuing year.

Honors for Americans.—The appointments of Mmes. George Cornwallis West and Jennie Blow as Ladies of Grace of the Order of St. John of Jerusalem, and Mr. J. J. Van Alen as an honorary Knight of Grace is announced, on account of their work in connection with fitting out the American hospital ship *Maine*, and a field hospital for South Africa.

Astley Cooper Prize.—Under the will of the late Sir Astley Cooper, Bart., a sum of money was left in trust, which should yield £300, to be awarded to the author of the best essay or treatise on "The Pathology of Carcinoma, and the Distribution and Frequency of the Secondary Deposits Corresponding to the Various Primary Growths." This prize is awarded triennially, full particulars of which will be found on reference to the advertising columns of the *Medical Press and Circular*. The competition is open to all members of the medical profession, except to the staffs of Guy's and St. Thomas' Hospitals. Particulars regarding other conditions to be complied with can be obtained on application to Dr. Newton Pitt, Guy's Hospital, London.

Two Dispensing Accidents.—A terrible triple mishap is reported from Normanton (Yorks), where three children have succumbed after taking powders supposed to contain santolin, but which there is reason to suspect contained

strychnin. The powders were dispensed in the surgery of a local practitioner, and, on suspicion being raised, it was found that the strychnin bottle stood in close proximity to that containing santonin. The dispenser declares, however, that he made no mistake, and the inquest has been adjourned for an analysis of the viscera. A somewhat similar accident is reported from Sketty, near Swansea, where a young mining engineer died from the effects of carbolic acid sent out in error for medicine.

Lead in Drinking Water.—At a recent meeting of the Hunslet Rural District Council, the principal subject discussed was the alleged presence of lead in the water-supply of Middleton. The question had been raised by Dr. Buck in his annual report, which stated that the Middleton water, supplied from Morley, still acts on the lead when standing in the pipes overnight. Various samples had been taken during the year, and no improvement had been perceptible, and he was of the opinion that the matter should be brought before the Morley Corporation, with a view to its abatement. After discussion, it was agreed that the inhabitants of the district be informed that it was not desirable to use the water in the morning without first opening the tap and letting it run some time. The chairman said they must prepare themselves for a considerable waste of water.

CONTINENTAL EUROPE.

Appointment.—Dr. Karl Haeger and Dr. Frederick Egger have been appointed extraordinary professors of medicine in the University of Basel.

Hospital for Skin Diseases.—Through the liberality of Madame Andre Nottebohn a hospital for skin diseases, which included a department for light-treatment, has been established at Antwerp. Dr. Francois has been appointed directing physician.

A Woman-physician Leads in the Race.—In the province of Novosibkov, Russia, occurred four vacancies for district physicians. Over 80 applications were received. Among those selected was also a woman, Mrs. Lishin, who graduated from the Medical Faculty of Paris.

Italian Recognition.—The Italian Government has tendered Dr. Eugene Wasdin, of the United States Marine-Hospital Service, the Cross of Officer of the S. S. Maurizio et Lazzaro, in recognition of his services in verifying and confirming the Italian studies and discoveries regarding the nature of yellow fever.

Death of Dr. Rocha.—Dr. Augusto Rocha, professor of clinical medicine in the University of Coimbra, and editor of the *Coimbra Medica*, has recently died of aneurysm of the ascending aorta. He was born at Coimbra in 1849, studied medicine in the university of that city, and took the degrees of licentiate, and a few months later of doctor, in 1876. He was appointed professor in 1882. He was the author of numerous contributions to medical literature, among which may be mentioned monographs on the Intravenous Injections of Chloral in the Treatment of Tetanus, an Investigation of the Typhoid Bacillus in the Drinking-water of Coimbra, Studies on the Nervous System, and papers on medicolegal subjects.

Meeting of the Medical Society of the City of Zurich, held on February 2, 1901.—Prof. Schlatter presented a 17-year-old girl on whom, on October 5, 1894, (that is, more than 6 years before) he had resected a 10 cm. piece of the lower jaw because of a myelogenous sarcoma. At that time a prosthesis modelled according to Claude Martin's suggestions of vulcanized, hard rubber fitted to the natural jaw was inserted and fastened at either end by outer and inner platinum plates screwed to the bone. This first prosthesis (*prothèse immédiate*) was removed on November 3. Then on December 3, 1894, the patient received—after wearing a substitute prosthesis for several weeks—a definite prosthesis with teeth. This grasped at either end the rear molar teeth which alone were left. The fastening showed itself secure. After each meal the prosthesis was removed (at first by the nurse, later by the patient herself), cleaned and replaced. This final prosthesis has been renewed 4 times during the 6 years in order to keep pace with the

growth of the surrounding bones. The present results, both from a cosmetic and medical standpoint, are excellent. The only thing noticeable is the scar in the submental region. The functional results are so good that the patient can bite through an apple. Professor Schlatter, in discussing the advantages and disadvantages of the Martin *prothèse immédiate*, considered that its worst point was not so much the difficulty of disinfection as the dependence of the surgeon upon the dentist. The Bönnecken, Bartsch, and Stoppani models of jaw supports were then exhibited and discussed. Professor Schlatter prefers the Stoppani aluminum model. This is not simply composed of metal plates, but pierced strips, the lower edges of which are bent,—to give chin a support and to prevent its falling in. The advantages of the Stoppani prosthesis are: (1) The surgeon is always prepared without the help of a dentist to insert the primary piece, no matter how great the resection; (2) it prevents the falling in of the chin; (3) it permits easy cleaning and supervision of the wound surface; (4) it permits the taking of a cast of the jaw without removal.

In conclusion Prof. Schlatter presented a 34-year-old patient on whom he resected both maxillary bones on September 7, 1897. The cause was sarcoma, from which there has appeared no recidive. The peculiarity of the operation was that the right common artery was temporarily ligated to perform the operation. (Prof. Schlatter's article on this operation is soon to appear in the *PHILADELPHIA MEDICAL JOURNAL*). The patient has wore for three years without trouble a prosthesis which acted as substitute for the right and part of the left hard palate, which supported the left bulbous and to which was attached a Schiltaky obturator. The result has been excellent. The nasal cavity is completely separated from the mouth. The double seeing due to the sinking of the left eye was cured by the projections on the prosthesis. The "lallend" speech, due to a drawing of the soft palate to the front, was also cured by the prosthesis. Prof. Schlatter has ligated the carotids in two other maxillary resections. Once the ligature of the external carotid sufficed to stop the bleeding; in the other case the ligating of the internal carotid was also necessary.

Further, Prof. Schlatter reported a case of true bone growth in the thyroid (struma calcarea), in which he performed strumectomy. The 45-year-old patient (woman) had suffered since her twelfth year with a hard goiter. Because of the terrible dyspnea she was forced to seek surgical aid. Because of the severity of the attack the operation was hurried as much as possible. Local anesthesia by 4 Pravaz syringesful of 1% cocain-eucain solution, and 1.01 of morphium. Patient was in sitting position. Incision from one sterno-cleido to the other. The upper thoracic aperture was entirely filled by the bone-like tumor. While seeking to draw this up and out the patient became so asphyxiated that her head fell back, the face became pale, and the breathing ceased, the pupils dilated, the pulse became small. Thereupon tracheotomy was performed with difficulty, the operator piercing the goiter, and found the trachea, which was compressed into a ribbon against the spinal column. A König canula was inserted and pushed behind the tumor-mass down into the thorax and artificial respiration according to Silvester was begun. With the spontaneous respiration (after about 6 minutes) a hemorrhage occurred, which was stopped by ligatures. The goiter was now literally dragged up out of the thorax, which caused a fearful venous hemorrhage from the jugular. By manual compression and finally ligatures this was controlled and the operation completed, leaving the tracheal canula in place. The patient made an uninterrupted recovery. The examination of the goiter showed therein a dissemination of true bone.

Professor Schlatter reported further 3 cases sent to him for operation as appendicitis and which proved to be (1) perforated pyosalpinx; (2) duodenal ulcer, and (3) extra-uterine pregnancy. The first and third were cured. In the second case the perforation was not found and the patient died. An old appendicitis had caused the intestines to become so attached to each other and to the peritoneum that a clear conception of the case was impossible and the trouble was believed to have been due to these old processes. The Bode drainage was used, but in spite of this the patient died after about 24 hours. This is the third case in Zurich where the Bode drainage for diffuse purulent peritonitis has proven ineffective.

1.—Bennett in this lecture discusses particularly **varicocele** associated with certain nervous symptoms. As to the frequency of varicocele it is found to occur in about 7% of all males. Eighty per cent. are affected on the left side only, limitation to the right side only is extremely rare. The varicocele itself usually produces no inconvenience and no pain unless injured. The distressing symptoms and those which make operation most frequently necessary are the melancholy states of the patient's mind. Bennett finds these patients to be always unmarried, and to whatever class they belong they are sensitive and intelligent beyond the average. He has never known a dull, stupid, or uneducated person to suffer from these symptoms. Masturbation cannot be considered a cause of varicocele. He describes varicocele as of two kinds: First, that consisting of large tortuous veins generally confined to the cord, and, second, that consisting of masses of small veins clustered around the testicles. This latter variety checks the growth of the testicle. The small testicle is often thought to be due to atrophy, but this is not the case, for the organ has never been developed. In the hypochondriacal cases arguments from the moral point of view are of little benefit unless "in the first instance the conditions of life ordinarily led are entirely changed." If the patient himself is convinced that operation and cure of the defect will bring about relief, operation can generally be recommended without hesitation and with a good prospect of cure in 60% of cases. If relief does not follow the first operation no secondary one should be done. At the earnest written solicitation of two patients and their friends, Bennett has twice performed castration after operating for varicocele, but in each case, as he predicted, the patients were not benefited. In operating for varicocele the veins are not denuded of the fascia covering them, but are tied *en masse*. He advocates very strongly the ligation of the spermatic artery, maintaining that the vessels which accompany the vas deferens, together with the few small vessels which are derived from the subvaginal tissue, are sufficient to nourish the testicle. Bennett thinks that the ligation of the spermatic artery tends to prevent the fatty degeneration which is occasionally seen after operation for varicocele. [J.H.G.]

3.—It may be assumed that beyond a certain point, increasing density of population upon a given area, in the absence of hygienic measures, would result in increasing mortality, and that in proportion to the application of these measures, the mortality would diminish. It is recognized that the most important factor in the spread of pulmonary tuberculosis is predisposition, and predisposition can be acquired as well as be innate, and further that by hygienic measures the acquired predisposition and the innate disposition, and even the communicable entity of the disease itself, can be so controlled as to be kept in abeyance, and even to be permanently subdued. It is further recognized that the conditions under which it may be acquired are residence in impure air, particularly such as is not renewed often enough, crowding of persons together, absence of sunlight, and dampness. In susceptibility to phthisis, the power of resistance appears to be even more important than the power of

infection, or in other words, the prevention of loss of vitality or energy is most important. In cities the average **dwelling space of the inhabitants** has a closer relationship to their health than any other condition of health which is capable of statistical expression. If we could obtain a classification of only a portion of the population according to the amount of measured cubic space occupied and the ages and causes of mortality, we should perhaps be able to draw more definite and exact conclusions still. Typhus was formerly very prevalent under conditions of gro's overcrowding, and not only typhus, but other infectious diseases tend to diminish in prevalence with increase of cubic dwelling space. The phthisis death-rate shows a close relationship to density of persons in cubic space, and phthisis appears to stand almost in the same relationship to respiratory pollution as typhoid does to filth pollution. The respiratory diseases, apart from phthisis, are also influenced by impurities of the air, and afford some measure of their effects, just as diarrheal diseases, apart from typhoid, are regarded as bearing a relationship to impurities of the soil. The effects of insufficiently separating street blocks from each other—that is, of allowing streets to be made too narrow, displays itself as one of the causes of unhealthiness of unsanitary areas. The occupants of stable dwellings have a high birth-rate, a high mortality at all ages, and high death-rates from pulmonary diseases both of infants and adults, and from the zymotic diseases, especially diarrhea and diphtheria. These facts point to the effects of the vicissitudes of temperature affecting adults, and unhealthy conditions at home affecting young children in tropical countries. [J.M.S.]

4.—Doran reports a very interesting case of **pyonephrosis**, occurring in a woman, 38 years of age, in which the usual symptoms of pain and fever were entirely absent. The patient was well nourished, able to do all her housework, and only suffered pain and nausea when she put on her corsets. Blood had never been passed in the urine, and she had never had any symptoms of renal colic. Examination revealed a large movable kidney, not tender, and apparently containing fluid. This organ was removed through the peritoneal cavity and upon examination was found to be filled with pus, to contain a free calculus in the pelvis and several others in the calices. There was complete obliteration of the ureter. The patient made an excellent recovery. Doran does not think that this is a case of an original floating kidney with kinking of the ureter. [J.H.G.]

5.—Jardine repeats his former statement that in the **treatment of puerperal eclampsia by saline diuretic infusions** the essential part of the method is the infusion. His aim is to dilute the poison and get rid of it as quickly as possible—that is to treat the cause and not a mere symptom. He has recently had under treatment some half dozen cases of marked dropsy and albuminuria of pregnancy. By prompt purging with salts and the use of diuretics and milk diet they all except one escaped eclampsia. If by the establishment of diuresis one can prevent the fits, it is reasonable to suppose that they can be cured by the same method. Besides the diuretic effect when the drugs are given subcutaneously, there is obtained a dilution of the poison and a stimulation of the patient. In other words the same effect is obtained as in the treatment of septicemia by saline infusions. As to the obstetric treatment of the condition, Jardine's experience teaches him not to interfere if labor has not begun. During the first stage, if the fits cease, dilatation may be left to nature, but if they recur the uterus should be emptied as quickly as possible. During the second stage delivery should be effected at once. Kerr has collected all the cases of puerperal eclampsia treated in the Glasgow Maternity Hospital during the last fifteen years. The death-rate among the cases treated by chloroform, chloral bromide, and veratrum viride, was 47%. Since the saline-infusion has been added to the treatment the rate has fallen to 17%. [W.A.N.D.]

6.—Eder records a case of **puerperal eclampsia treated by morphin** successfully. He claims that when the medical attendant is brought face to face with a patient in convulsions, whether these be before, during, or after labor, no remedy is so quickly and certainly sedative as morphin hypodermically administered. [W.A.N.D.]

7.—Marsh and Monsarrat report a case of **multilocular cystoma of the omentum**, occurring in a child aged one

year and eight months. This case was at first looked upon as one of tuberculous peritonitis, as the fluid seemed to be free in the peritoneal cavity, producing dullness in both flanks. The abdomen was tapped repeatedly and quantities of light colored serum removed. At the last two tapings blood was found in the fluid. After the last tapping the flanks were found resonant, although there was still the evidence of fluid in the upper part of the abdomen, hence, laparotomy was advised and done. There was found a large cyst of the omentum with many smaller ones involving nearly the whole of this portion of the peritoneum. The child made a very good recovery. [J.H.G.]

8.—In undertaking the use of chemical culicidal agents it appears that the most profitable time for their employment would be during the dry season. During the wet season, with heavy rains much actual washing away or dilution would occur; however, nature's own culicicides, in the form of tadpoles, water beetles, etc., may be enabled to spread from pool to pool, and assist in the **destruction of anopheles larva**. Koch has been the chief advocate of the proposal to effect the **ridance of ague** by means of quinin. It is generally admitted that although the administration of quinin causes a rapid disappearance of the malaria parasite in its asexual form from the blood, the sexual forms can still be found, even after long periods of quinin-taking. It is clear, therefore, that some better drug than quinin is needed for stamping out ague, inasmuch as it is by the sexual forms that the disease is spread by means of the gnat. Durham believes that arsenic is the drug that has best repute for compassing the destruction of these forms. In the treatment of an individual suffering from ague in a region where he is likely to be a danger to his fellow men, every endeavor should be made to prevent the development of sexual parasites in his system. For the patient's own safety he must be given quinin in some form or other; at the same time, for the safety of the community, the administration of some drug, such as arsenic, should be commenced. [J.M.S.]

1.—The abstract will appear when the lectures are completed.

2.—Ransome and Foulerton in an article defined "**the influence of ozone on the vitality of some pathogenic and other bacteria**." They review the literature of the bactericidal action of ozone, laying special prominence on the work of Downes and Blunt, who have shown that the blue and violet rays of the spectrum have a greater influence upon destroying the vitality of the bacteria than the red rays. The authors have conducted a number of experi-

ments, first to determine the action of ozone upon the vitality of certain bacteria, and second to ascertain whether the virulence of the tubercle bacillus is influenced. The first experiment consisted of subjecting cultures of various bacteria to a current of ozone and atmospheric air. Control tests were made at the same time. These experiments showed that the growth of two out of seven species of bacteria was slightly retarded upon exposure to the ozone. The second experiment consisted of exposing bacteria to ozone in the absence of organic matter. Small blocks of plaster-of-Paris were inoculated with stock cultures of different bacteria. The blocks were then placed in culture tubes and subjected to a current of ozone. Control experiments were also made by inoculating plaster-of-Paris blocks; then placing these in culture tubes, and subjecting them to a current of air. The ozone had no effect upon the vitality of the microorganisms. The third experiment consisted in exposing various cultures of bacteria, after having placed these upon porcelain, to the action of ozone, produced by passing oxygen under pressure from a cylinder over a powerful ozonizer. The bacteria were not affected; their growth was not impaired, and the chromogenic organisms did not lose their power of producing pigments. The fourth experiment consisted of passing ozone through fluid cultures of microorganisms. Milk was used as the culture media. This experiment showed that the bacteria lost their vitality. The fifth experiment was made in order to determine whether or not ozone had any influence upon modifying the virulence of the bacillus tuberculosis. It was shown that the virulence was not changed. The authors have drawn the following conclusion: That ozone in a dry state does not affect the vitality of the bacteria experimented with to any appreciable degree; nor does the action of ozone modify the pathogenic virulence of the bacillus tuberculosis; and, finally, the activity of bacteria is hindered when ozone is passed through a fluid medium containing the microorganisms in suspension. [F.J.K.]

3.—Will be considered editorially.

4.—Angus gives the results of major amputations in the Royal Infirmary, Newcastle-upon-Tyne, during the year 1899. There were 67 amputations, 32 for injury and 35 for disease. The mortality for the whole was 9.03%. Of the 32 cases of injury four died, a mortality of 12.05%. Of the 35 amputations for disease two died, a mortality 5.07%. [J.H.G.]

5.—Hunter in an article entitled **The method of distinguishing bacillus coli communis from bacillus typhosus, by the use of neutral red**, comes to the following conclusions: (1) That the power of reducing neutral red is possessed by the bacillus coli communis to a marked degree, and superb canary yellow fluorescent color of the culture media is produced; (2) this same reaction is produced by the so called bacillus enteritidis of Gaertner; (3) this reducing power is not possessed by the bacillus typhosus; (4) the reaction is not given by other pathogenic microorganisms; (5) with accuracy, the diagnosis as to the presence of bacillus coli communis is possible within from 12 to 24 hours, by means of the neutral red reaction. The author, so far as his experience goes, states that by means of the neutral red it is possible to diagnose the true coli group from the typhoid group of microorganisms. [F.J.K.]

6.—Foster reports a case of **influenza complicated with meningitis** in a woman 54 years of age. The illness began on January 29, with pains in the back and legs, sore throat, and headache. On the following day the symptoms were more pronounced, the temperature was 103.5° F., the pulse-rate was 95 per minute, and the respirations were 25 per minute. On February 1 the headache became more intense, and nausea and vomiting developed; the temperature was 104° F., pulse-rate 90, and the respiratory frequency 36. On the evening of the same day the temperature fell to 97° F., and the patient had some difficulty in speaking and swallowing. On the following day the temperature again rose to 103.5° F., the pulse-rate was 72, and the respiratory rate 50. Rigidity of the muscles of the neck developed, the patient was unable to talk or swallow, and a state of stupor set in. There was partial paralysis of one-half of the face, strabismus appeared, and there was a muscular tremor involving the face, arms, and legs; retraction of the head was striking; death occurred on the morning of the third of February. The author states that there was no doubt as to the diagnosis of influenza, followed by meningitis. A post-mortem examination was not made. [F.J.K.]

7.—Treated editorially.

8.—Sackville reports an interesting case of fracture of the sternum, due to pressure exerted on the two shoulders. He calls attention to the peculiarity of the force which produced this fracture. The line of fracture was obliquely across the manubrium and only gave rise to pain when the pectoral muscle was in action. [J.H.G.]

9.—Riley reported a case of **cerebrospinal meningitis** in a girl of 5 years of age, who had always been in fairly good health. The disease developed suddenly with the symptoms of vomiting and headache followed by convulsions; the temperature rose to 103.5° F. and remained high several days. On the fourth day retraction of the head and slight opisthotonos developed. The superficial and deep reflexes were abolished except that Babinski's sign was present. The spleen was not enlarged and the abdomen was retracted. A mixed erythematous and petechial rash appeared on the trunk and extremities. This rash appeared on the fifth day. The patient complained of pain in one knee and there was a slight swelling of the dorsum of the foot. The optic discs were congested and pupillary reaction to light was somewhat retarded. During the acute stage of the disease the temperature range was of the inverse type, but as the patient began to improve, the morning temperature was lower than the evening temperature. For a while the respirations were of the Cheyne-Stokes type. Slight ptosis of the left eyelid and photophobia developed. As the disease progressed the reflexes returned, and the skin became hyperesthetic, but retraction of the head increased; vomiting was an occasional symptom. The symptoms began to subside 4 weeks after the onset; during this period great emaciation developed; the total duration of the disease was 3 months. The treatment consisted in the application of ice-bags to the head and neck and in the administration of potassium bromid and iodid; small quantities of brandy were given as a stimulant, and during the period of vomiting, food was administered per rectum, small doses of calomel were used to keep the bowels opened. The case is of interest because Babinski's sign was present, herpes labialis and headache were absent after the onset of the disease. The origin of the illness was very obscure. [F.J.K.]

10.—Peters advocates the use of **suprarenal extract for the relief of pain** in some conditions. He reports 4 cases in which pain was relieved by the administration of this animal extract. He found that the most efficient preparation was obtained by dissolving tabloids of the dried gland in boiled water; the solution was then filtered and this was administered. The author advocates a 10% watery extract; the first case in which he used this preparation was one of recurrent scirrhus of the breast in a woman, 89 years of age; the local application of suprarenal extract in this case gave the patient much relief. The second case was one of stricture of the esophagus occurring in a woman; pain developed after the passage of a bougie, which was relieved by a teaspoonful of the 10% aqueous extract of suprarenal capsule; the dose was repeated every evening before going to bed. The third case was one of tuberculosis of the larynx, occurring in a man 34 years of age; the suprarenal extract was used in the form of a spray. The fourth case was one of periodontitis; the extract was applied every two to six hours; the patient in this way was given much relief. [F.J.K.]

New York Medical Journal.

March 16, 1901. [Vol. lxxiii, No. 11.]

1. Congenital Dislocation of the Shoulder with Report of Two Cases of Dislocation Posteriorly. DANIEL W. MARSTON.
2. The Representation of Biliary Calculi by the Röntgen Rays. CARL BECK.
3. Substitute Feeding of Infants upon Milk Modified According to Prescription in Laboratories. W. P. NORTHRUP.
4. The Specific Treatment of Acute Dysentery. WILLIAM J. CRUIKSHANK.
5. The Pathology of Intra-Uterine Death. NEIL MACPHATTER.
6. Angelioma Cysticum of the Nose. HENRY LEWIS WAGNER.
7. A Simple Apparatus for Modifying Cow's Milk. CHARLES HERRMAN.

1.—Marston discusses the pathology of **congenital dislocations of the shoulder**, and reports 2 cases of posterior dislocation. He thinks this condition due to traumatism at birth or in utero, or to some prenatal diseased condition of the joint. He does not think that paralysis is a primary etiological factor of the dislocation, but rather a result of the condition. When the patient is under 3 years of age reduction by manipulation should be attempted. Failing in this, the operation suggested by Phelps (Transactions American Orthopedic Association, 1898) should be employed. [J.H.G.]

2.—Carl Beck, of New York, claims to have showed the first undisputed **skiagraph of cholelithiasis** in living patients. A further experience in making these skiagraphs has enabled him to modify the principles he originally set forth. The correctness of the statement that the **chemical composition of the calculi** will have much to do with their clearness of definition has been found to be correct to some extent only. He has succeeded in fixing the **common biliary calculi** even when they are as small as the head of a pin. Even calculi of the hepatic ducts are shown. The **mixed bilirubin calculi** are less permeable to the rays than all the other varieties. Those of pure cholesterin show well, while the **stratified cholesterin calculi** show less permeability to the rays. He attributes this success to the excellent quality of the tubes he employs. They must bear a 15 inch spark for 5 minutes without coming too hot. The tubes he has used for reproducing biliary calculi display their energy only as long as they are new. The position of the patient is an important factor. He should lie on his abdomen with three pillows under the clavicles, for this elevation permits the protrusion of the gallbladder, and brings the calculi nearer to the photographic plate. The direction of the rays should be such that they should form an angle of about 70° with the plate, and the tube should be as near the abdomen as possible. The disadvantage of oblique irradiation is that the calculi appear larger than their natural size. When a protrusion palpable in the region of the gallbladder indicates that it projects from the liver, direct irradiation is to be preferred. The bowels should be thoroughly evacuated before irradiation. [T.L.C.]

3.—Northrup publishes his views upon the substitute feeding of infants with milk modified according to the prescription in laboratories. He emphasizes the necessity for a thorough examination of the sources of all milk for general use and insists that the laboratories supplying this milk should be under the most careful supervision. The modification of milk consists in the transformation of the proportion of cow's milk to the proportions of woman's milk, and in transforming a slightly acid milk to one of slightly alkaline reaction, in preserving it from contamination and making it as nearly as possible like a mother's milk. It is to be remembered that cow's milk is approximately 4% of fat, 4% of sugar, and 4% of proteids. In consequence then it is necessary to remember three formulas: (1) Feeding for the newborn, adapted to the majority, should comprise 2% of fat, 5% of sugar, 0.75% of proteids; (2) "Low-average breast-milk" should contain 3% of fat, 6% of sugar, and 1% of proteids; (3) "high-average breast-milk," 4% of fat, 7% of sugar, and 2% of proteids. These modifications should be changed gradually and frequently by small fractions from one to another. At the age of from 8 to 10 months it is time to make the proportions approximate that of the whole cow's milk; in other words, wean the child. The feeding should be all milk for the first year, and mostly milk for second year. [T.L.C.]

4.—W. J. Cruikshank concludes his paper upon the **specific treatment of acute dysentery**. His conclusions are that dysentery is a disease of great gravity, and that it is both contagious and infectious; that it is caused by the introduction to the system through food, drink, and also through the air, of a specific microorganism, the identity of which seems to be still in doubt. He states that dysentery is one and the same disease in whatever latitude it may be found, and its varieties represent merely the difference of intensity of the morbid process. The majority of therapeutic agents which have been employed are useless, and even harmful. Sulphate of magnesium, properly administered, in the acute form of dysentery acts as a specific. [T.L.C.]

6.—Henry Lewis Wagner has devoted considerable

time to the study of the classification of the various cysts of the nose. His cases were studied in a boy of 9 years and a woman of 28. Both presented practically the same condition. Microscopically the nasal passages present no pathological condition other than a single bluish gray tumor obstructing the entire posterior portion of one side of the nose and protruding somewhat into the nasopharyngeal vault. The tumor shows greater elasticity to the touch than any other found within these limits. It is movable and attached to a small base. It will rapidly form again after removal unless the seat of the cyst is thoroughly destroyed, as with the galvanocautery. Microscopically the ciliated columnar epithelium covered nearly the whole of the external part of the growth with the exception of a small portion which consisted in squamous epithelium, probably produced by pressure or by continuation of the mother-stratum. No glands are to be found in any of the sections, but there are a large number of venous bloodvessels, some of them enlarged and running parallel with the sac. Some large venous sinuses are also seen. On this account he terms this growth angioma cysticum. Upon chemical analysis the fluid of the cyst is found to possess an alkaline reaction and a specific gravity slightly lower than that of blood-serum. It has a brown color that is partly due to **lupien** and partly derivative from hemoglobin. Serum albumin was found in larger quantities; only a few red blood-corpuscles were detected. A coagulation of the whole fluid occurred a very short time after removal. [T.L.C.]

Medical Record.

March 16, 1901. [Vol. 59, No. 11.]

1. The Treatment of Gonorrhea with Frequent Irrigations of Hot Decinormal Salt Solution. CHAS. E. WOODRUFF.
2. A Whistle in the Esophagus. A. E. ISAACS.
3. The Treatment of Colitis by Valvular Colostomy and Irrigation. P. R. BOLTON.
4. The Ovary; Its Relation to Normal Functions and to Pathological States. S. W. BANDLEY.
5. The Use of Suprarenal Capsule in Hemoptysis. WILLIAM B. KENWORTHY.

1.—Charles E. Woodruff recommends frequent irrigation with hot decinormal salt-solution in the treatment of gonorrhea. He employs a simple short glass tube and has seen no harm come from using as much as a quart of hot salt-solution every hour. He has found that if the discharge keeps up for more than 10 days under this treatment, the irrigations are not properly done. In a study of 98 cases he has found that the average time of cure is 12½ days; about 30% lasts 7 days; 30% 11 days; 20% 17 days; 10% 20 days, and 10% over 3 weeks. Though the actual duration of the symptoms is less than this, as each case remained in the hospital 2 or more days after the symptoms disappeared. In 5% all symptoms disappeared within 2 days. As a rule there was marked reduction within a week and total cessation in from 10 to 14 days. It is well known that early cessation of the discharge is really a danger in any treatment, but it may be overcome by carefully explaining the conditions to every man. Woodruff gives each patient an astringent injection to use for 2 or 3 weeks after leaving the hospital. In his 98 cases there were not more than 6 or 8 relapses. [T.L.C.]

2.—A. E. Isaacs, of New York, reports a case of a child who swallowed a whistle 2 days before he saw him. At first the symptoms had been very urgent, but when seen they had so much improved that what remained could be very well accounted for by the irritation from previous attempts to dislodge the foreign body. A radiograph showed that the whistle was lodged in the esophagus, although an esophageal bougie and a bristle brobang were used without revealing the foreign body. After expere menting with various instruments, Isaacs succeeded in removing the whistle with a "coin-catcher" or a "hinged-bucket" [T.L.C.]

3.—P. R. Bolton discusses the treatment of colitis by valvular colostomy and irrigation. In 1885, Keith recommended the treatment of some forms of colitis by diverting the fecal current and sparing the mucous

membrane of this part of the intestine from contact with it by establishing an artificial anus in the cecum, which should also facilitate local applications to the mucous membrane. This plan has been carried out with gratifying results in a number of cases. The treatment, however, is radical and there are positive risks entailed. The writer reports the following case, in which a modified form of the treatment outlined was employed. The patient was a male, of 42 years, with negative family history. Eight weeks before being admitted to the hospital, and without assignable cause, he developed a **severe diarrhea accompanied by fever and prostration**. This persisted in spite of all treatment. The stools were blood-stained and contained a great deal of mucus, and numbered from 16 to 23 in the 24 hours. No amebae were found. The patient lost 31 pounds in weight. The first step in the treatment consisted in performing of a **cecal colostomy**. A 1½ inch incision was carried through the abdominal wall parallel with the right Poupart's ligament, and an inch internal to its outer part. The cecum at once presented. A point was chosen in its anterior band and the intestine opened sufficiently to admit a fair-sized soft-rubber catheter. Three tiers of sutures placed above and below this orifice served to enclose the cecal wall. The ends of those last introduced left long and carried through the margin of the abdominal incision, brought the cecum forward into close contact with the abdominal wall, and were utilized to close the external wound, being reinforced by a silkworm gut suture at each angle. Healing of the abdominal wound occurred promptly. The after treatment occupied 4 weeks, but the patient was confined to bed for only half this time. The diet at first was composed entirely of **proteids**, and **salol** and **castor oil** were given every 3 hours in small doses. Toward the close of the treatment a mixed diet was allowed. Irrigation of the colon was begun at once. Several quarts of **.01% solution of silver nitrate** were injected through the catheter. This was followed by a **.5% salt-solution**. For the first 3 days this washing was done twice a day, for the next 11 days once a day, and the strength of the silver solution increased to .02% for the remaining time every other day. The catheter was removed after the seventh day except at the periods of washing, and in the intervals there was absolutely no leakage. His weight increased 10 pounds. Complete recovery followed. A small ventral hernia has appeared at the site of the operation, which has led to the author's decision to adopt in future the intermuscular incision of the abdominal wall. [T.L.C.]

4.—Bandley has made an exhaustive study of the **ovary and its relation to the normal functions and to pathological states**. He remarks that one of the functions of the normal ovary is the production and expulsion of ova capable of being fecundated. It is probable that after birth no new ova are formed from the germinal epithelium. After puberty the vitality of the ovary is revealed by its ability to bring these ova to a stage which may be called **right**. For the expulsion of an ovum from the **graafian follicle** a gradual increase in size of the follicle takes place depending partly on an increase in the amount of liquor folliculi. The cells of the follicle epithelium undergo fatty degeneration, and the internal layer (the tunica interna) shows an increase in the size of the cells and a decided development of the bloodvessels. As a result of this fatty degeneration the ovum is freed from the cumulus oöphorus. The most prominent point of the follicle is poor in blood-supply and furnishes the so-called stigma folliculi, at which place an opening is formed for the escape of the ovum. After ovulation the ovum is thrown out into the abdominal cavity, ultimately finding its way into the uterus. It is not necessary that the tube should grasp or surround the ovary. Lode has shown that an ovum finds its way through the tube into the uterus in 30 hours. Menstruation is the periodic loss of blood from the uterus or from any mucous membrane and may be divided into three periods: the premenstrual, the menstrual, and the postmenstrual. The premenstrual period is characterized by a swelling of the endometrium, which may measure from 6 to 7 mm. in thickness. During the menstrual period the superficial capillaries are greatly dilated, and an exit of blood-elements not dependent upon a bursting of the capillaries goes on for several days. The bleeding occurs partly through diapedesis, and in strong bleedings through rhexis. There is little or no destruction of the mucosa, only a very slight fatty

degeneration of the epithelium of the uppermost layer. The changes in the tubes, if any, are slight. The postmenstrual period comprises 14 days, during which the mucous membrane returns to a thickness of 3 mm. During this time all cells not capable of further growth are thrown off, and the epithelium, only partially denuded, is regenerated. A regeneration concerns the stroma, the glands, and surface epithelium, reaching its height on the fourteenth or fifteenth day after the beginning of menstruation. Ovarian secretion is the direct cause of this periodic swelling of the mucosa, and it continues, if fecundation has not taken place, to exert not only a local but likewise a stimulating influence on the general and sexual organs. On the occurrence of pregnancy this secretion causes a further development of the uterus and the decidua and plays an important part in the process of labor. It stimulates the functions of the breasts, exerts a decided constitutional stimulation and is the cause of many of the pathological conditions occurring before and during labor. Ovulation and menstruation are related only in that both are the result of the secreting functions of the ovary, and are in no wise connected as regards cause and effect. Ovulation as a rule occurs from 4 to 8 days before menstruation, but it may occur at other periods, as ripe ova may be present at almost any time. Since ovulation may occur without menstruation, but the latter never without the former, we have here an evidence that a certain functional activity of the ovary is necessary to stimulate the mucous membrane from its periodic changes. Menstruation is simply an evidence that a fecundated ovum is not present in the tube or in the uterus. A proof of the direct influence which the ovum exerts upon the decidua is shown by the manner in which the space formed by the embedding of the ovum is filled up. It may be taken for granted that the ovum embeds itself in the decidua, and that an active growth of the latter up to and surrounding the ovum, with a formation of the so-called decidua reflexa, by no means takes place. Another of the functions, then, of ovarian secretion is to be found in its stimulation of the round cells of the stroma to growth and to the formation of decidua cells. This secretion is a stimulus likewise to uterine contractions, and is the probable cause of the contractions normally occurring during labor. The action upon the uterus at the end of pregnancy of this accumulated secretion is probably the cause of labor-pains. The action of the ovarian secretions upon pulse-tension and its effect upon the mucous membranes of the body generally are evidenced by the congestion of the vocal cords during menstruation, so that during this time the singing voice is poor. The secretion of intestinal mucosa is also greater, there is increased perspiration, the lower turbinated bones are swollen, and the eyes suffer limitations in power. Bandley also emphasizes the trophic action of the ovarian secretion as evidenced by the numerous experiments upon transplantation of the ovaries. It is also shown in the various disorders of menstruation, such as amenorrhea, in which case there are frequently found poorly-developed ovaries; menstruation, if present, is unaccompanied by pain, and the girls have irregular, weak, or eventually no menstruation. Although these persons may be well-developed, yet they show poorly developed genitalia. The frequent occurrence of amenorrhea and uterine hypoplasia in chlorotic girls is an interesting link, associating the ovary as a secreting organ with the vital functions of the body. A further evidence of the influence of ovarian secretion upon the body in general may be found in its relation to osteomalacia, occurring as the disease does so frequently in pregnancy. Bandley also believes that the ovarian secretion is responsible for the development of eclampsia, and for the occurrence of chorea, especially developing at the period of puberty and in the early months of pregnancy. [W.A.N.D.]

5.—William B. Kenworthy reports a case of hemoptysis treated by suprarenal extract. Kenworthy states that in the 14 cases in which this remedy has been used to control hemoptysis in no case did it fail to accomplish its purpose, and in only one case did the hemorrhage continue for 15 minutes after the administration of the first powder. In his own case he administered the drug in 3-grain capsules, one every half hour until 3 were taken. Then one every two hours until 3 more were taken, then one three times a day for a week, to be taken dry on the tongue, chewed and swallowed without water. [T.L.C.]

5. A Preliminary Note on the Relation of the Form of the Tubercle Bacillus to the Clinical Aspects of Pulmonary Tuberculosis. HENRY SEWALL.
6. Rhinoscleroma. H. JARECKY.

1.—Elsner, in his recent experience with erythromelalgia, reports 3 cases associated with Raynaud's disease, and gives the great variety of diseases which claim erythromelalgia as an attendant. Schwenck's case, with ascending degeneration of the posterior columns of the cord; Woodnut's case was associated with myelitis; Collier reports 10 cases associated with various spinal, system, and indiscriminate lesions; Auerbach reports 2 cases, in one of which a postmortem examination revealed degenerative changes in the posterior nerve-roots of the lumbar and sacral nerves without degeneration in the cord substance, while the bloodvessels were found normal. This is the only postmortem of a case of erythromelalgia on record. Neider reports a case of erythromelalgia with eye symptoms prominent, choked disc with vascular dilatation; Eulenberg, one case of brain tumor with hemorrhagic retinitis and consequent changed visual field; Hoffman mentions an interesting case of akromegaly associated with erythromelalgia, in which the patient was 23 years of age. She had had erythromelalgia since her sixth year, when finally the characteristic changes in the hands and feet followed; Henoch's case was one of erythromelalgia following hemiplegia and hemihyperidrosis, death finally resulting from angina pectoris; and Levy reports a case resting on a hysterical basis, cured by hypnosis, in which erythromelalgia was associated with Raynaud's disease. [T.M.T.]

2.—In Abrams's treatment of the heart in typhoid fever he sets forth the following theories in explaining the action of the cold bath treatment: (1) It possesses a powerful stimulating action on the circulatory apparatus and nervous system; (2) it exerts an antipyretic action; (3) it stimulates the nerve centers presiding over the functions of respiration, circulation, digestion and excretion; (4) the flux and reflux of blood between the periphery and viscera are facilitated; (5) leukocytosis is produced. He advocates the use of the carbonated bath (S. Holt method) in place of the cold bath and knows no means better adapted for maintaining the vigor of the heart in typhoid fever, pneumonia and other infectious diseases. The reduction of temperature after the carbonated baths is relatively slight, and such reduction is evoked by dilatation of the subcutaneous vessels. If, however, we regard temperature reduction as a necessity, then we may alternate the carbonated with the cold baths, or we may even incorporate the ingredients necessary for generating the carbonic acid in the cold bath. He also describes the friction bath as follows: The patient is first rubbed or sponged with alcohol and this is followed by vigorous cutaneous friction until the skin glows. In nearly all cases where the friction bath was employed in lieu of the cold bath the temperature reduction was slight, but the stimulating effect upon the heart and nervous system was pronounced. Another treatment is the siphon method in which the patient is prepared in the usual manner for taking a sponge bath. The siphon bottle containing the carbonated liquid is gradually discharged over the surface of the body, notably in the thoracic region. The siphon may be immersed in hot water if desired. This method has reduced the pulse 10 to 20 beats a minute, which rate is maintained for a varying period of time. [T.M.T.]

3.—The results of Connor's study of three cases of thoracic aneurysm treated by subcutaneous injection of gelatin have not been very satisfactory. In two of these cases three injections were given, in the other seven. In the first two it was discontinued on account of the severe pain following. In the other the pain was only slight. In

the case that received seven injections there was very slight improvement. In one case a slight increase in the symptoms was noted, while the third case died of rupture of the aneurysm while under treatment and the autopsy showed no evidence of recent thrombosis formation, although the condition, that of large sac with a small communication with the aorta, was an especially favorable one for clotting. His experience in these three cases has convinced him that, whatever the curative value of the treatment, its usefulness is seriously impaired by the severe pain which frequently follows the injection. [T.M.T.]

4.—Craig in his observations upon the amebae coli and their staining reactions demonstrates the following: (1) That vacuolization is a degenerative process, as the young amebae show no vacuoles, the full grown healthy ones, few, while the amebae in which they are the most numerous are degenerate bodies, showing neither a nucleus nor inclusions of any kind; (2) that there occur in all but the degenerate forms of amebae, small, round, or oval unstained areas, uniform in appearance, and most numerous in the large full grown forms, and entirely absent in the vacuolated shells of amebae. The areas resemble similar areas observed in stained, segmenting malarial plasmodia, which are, in them, due to the young spores, which take the stain but faintly. Reasoning from analogy, it may be that these areas in the amebae are also spores; (3) that in the protoplasm of the amebae there occur peculiar structures, evidently not bacterial in nature, the significance of which it is impossible to decide. It may be that they are certain crystals which occur in the feces and which have been absorbed by the amebae; (4) that degeneration of the amebae takes place in two ways, *i. e.*, by vacuolization and by fragmentation. [T.M.T.]

5.—Sewall, in his studies on the relation of the form of the tubercle bacillus to the clinical aspects of pulmonary tuberculosis, comes to the following conclusions: That short, deeply-staining rod or chain of rods of moderate length is the usual form in many active cases. The long rods, particularly if irregularly broken, betoken a milder process, and the chains of sporelike beads characterize the very chronic cases which make us wonder at their tenacious hold on life. If there be a good form of the tubercle bacillus it is, as seems to us, a rather long, slender rod, ill-staining, or staining irregularly, as if the body of the microbe were irregularly corroded on the sides. It is found in cases apparently passing on to cure. Sputa of the same individuals examined month after month have seemed to me to vary in their bacillary characters with the state of the patient as regards the disease. [T.M.T.]

1. The Story of the Boston Society for Medical Improvement. J. G. MUMFORD.
2. Notes from the Neurological Department of the Massachusetts General Hospital. W. E. PAUL.
3. Intestinal Anastomosis. CHARLES G. CUMSTON.

2.—Paul reports the case of a woman, 51 years old, who was suffering from bulbar paralysis with hemiplegia and astereognosis. Eleven years previous to the author's examination, the woman suddenly became unable to talk, but in brief time the disability disappeared, leaving no traces of the attack. A year later, speech was arrested in the middle of a sentence, she felt dizzy, and the left arm became numb and powerless. Consciousness was retained, vision was not disturbed, and there was no vomiting. At the end of 3 months she was up and about with some improvement in all her symptoms. Ten years after the attack, the patient talks in a mumbling fashion; she cannot whistle, and she drools on her pillow at night. There is typical bulbar speech; the left hand cannot make fine movements; pain sense is decidedly blunted over the left upper extremity; space sense is not lost but is impaired; pressure sense is altered; muscle sense is preserved; objects are unrecognized by the left hand; the knee-jerks are normal, there is no ankle clonus, and the plantar reflex is absent in both feet. [J.M.S.]

Journal of the American Medical Association.

2.—G. Oram Ring reports a case of paresis of the external recti associated with irregular tabes occurring in a man, aged 30, otherwise healthy and with a negative family history. Within a period of two years the only ocular manifestation was paresis of the left external rectus muscle. The affection was supposed to be dependent upon a specific infection, although the iodides had but little effect. The best result, although only palliative, was obtained from chloride of gold and sodium. [M.R.D.]

3.—Edward Jackson makes a plea for a more complete and exact study of ocular refraction and corneal curvature before and after extraction of the lens for myopia. He presents a table showing the diopters of myopia before operation, the anticipated theoretical change for axial myopia, the average change noted, the maximum and minimum changes, and a number of cases of each degree of myopia, the cases varying from 10 diopters to 35 diopters. The author furthermore discusses the optical changes produced by removal of the crystalline lens in myopia due to excessive corneal curvature, in that due to excessive refractive influence of lens, and in myopia due to increased length of axis. [M.R.D.]

4.—Howard S. Anders, in an article on the clinical features of epidemic influenza, gives his observations, which are based upon an analysis of 128 cases. The most common onset includes certain symptoms common to the cerebrospinal and respiratory forms. The early symptoms are headache, pain in the back and limbs, and extreme prostration for the first 5 or 7 days. Especially those cases characterized by symptoms relative to the respiratory tract showed intense prostration. Congestion of the conjunctivae was a symptom well characterized at the onset. In the mild cases there was no fever, while in the more severe form the temperature rose above 102° F., its elevation continuing during the first 2 or 3 days. The highest temperature reached was 105° F., occurring in 2 uncomplicated cases, one in an infant 14 months old, the other in a woman 72 years of age. The decline of the fever was by rapid lysis, and in only one case was the fever continuous for a period covering 10 days. During convalescence, subnormal temperature was of frequent occurrence. The symptoms referable to the cerebrospinal system were the following: Severe pains in the loin-nerves, and muscles; soreness of the sternocleido-mastoid and other muscles of the neck; cephalalgia; inflammation of one or more of the intercostal nerves, suggesting pleurisy; and in one case, there was enteralgia. Neuritis, affecting the plantar nerves of the left foot, occurred in one case; otalgia, facial neuralgia, and mental disorders were also observed. Conjunctivitis was a frequent concomitant of the influenza epidemic; 13 cases showed hyperemia and watering of the

eyelids; in 4 there was suppuration. In 2 cases purulent otitis media occurred; one developed in an infant, the other in an adult male. Many of the cases began with faucial, tonsillar and pharyngeal inflammation; severe laryngitis was the prominent manifestation in 7 of the cases; in almost every instance bronchitis developed, being especially severe in 23 cases; bronchopneumonia was associated in 5 cases, and dry pleurisy also in 5 of the cases. The symptoms referable to the gastrointestinal tract were the following: Anorexia was associated in nearly all the cases; the less important manifestations were coated tongue, nervous irritability of the gullet and stomach, precordial and epigastric distress, flatulency and sluggishness of the bowels. Palpitation of the heart, with signs of dilatation, occurred in two children and in an adult; bradycardia was frequently noted during the period of convalescence; vasomotor disturbance, in the form of depressing flushes, was a symptom observed in 3 women; only 2 cases of acute nephritis developed; herpes labialis was noted in 30% of the cases. The most important complications were lobar pneumonia, nephritis, peripheral neuritis, emphysema and cardiac dilatation. Dry tubercular pleuritis was of rare occurrence. Intermittent tertian malarial fever developed during the height of the disease in two instances, and recurrence of the attack of influenza occurred in 4 persons. The important sequels were the following: Unilateral sweating of the right side of the face occurred in one case; phlyctenular keratitis in a boy 3 years of age; erysipelas of the face in a middle-aged woman; melancholia in a female 52 years of age; total deafness in a girl 3 years of age; neuritis in one case. Many of the patients complained of marked physical prostration and lack of ambition after convalescence was established. From the standpoint of diagnosis, it was found necessary in some cases to exclude acute muscular rheumatism, follicular tonsillitis, measles, intermittent malarial fever, cerebrospinal meningitis and enteric fever. The author concludes the article by mentioning the climatic conditions favorable to the epidemicity of influenza. [F.J.K.]

5.—Valentine thinks that general anesthesia should be employed in all children under the fifth year unless some cardiac or pulmonary condition exists which is a contraindication. In older children local anesthesia is often very satisfactory. In the Hebrew race he thinks it would be much better if the operation were performed by a Hebrew doctor capable of observing the proper aseptic precautions. [J.H.G.]

6.—Freudenthal suggests the following plan of treatment for laryngeal tuberculosis: Relief may be given by the application of saccharated suprarenal gland to produce local anesthesia. Menthol-orthoform produces a longer local anesthesia, and has also curative properties. For the relief of dysphagia he recommends olive, almond or sesame oil; he has not as yet reached final conclusions as to the efficacy of phototherapy; heroin is recommended for the bronchial cough. He concludes the article by urging further investigation in this large field. [F.J.K.]

7.—Cobb mentions the value of electrolysis in the treatment of atrophic rhinitis. In typical cases it has a curative action so far as preventing the tendency to crust-formation and lessening the odor, but the discharge or the odor is not modified when nasal empyema is present. The best results are obtained by placing the needles comparatively near together; improvement in the condition is especially noticeable in the area corresponding to the application of the positive pole, and that improvement is due to the liberation of oxygen and chlorine or the acid reaction produced thereby; and finally, he cautions us never to introduce the needle of the negative pole beneath the membrane of the septum. [F.J.K.]

8.—The nature and treatment of vertigo are investigated by Corning. After a number of experiments, the author draws the following conclusions: 1. Primarily, vertigo is a derangement of perception. 2. Some impairment of consciousness is always associated with a derangement of perception. 3. Confusional conditions engendered in contiguous centers of higher mental action—cortical centers—produce the impairment of consciousness by the impairment of the functions. 4. Direct impairment of functional efficiency of the centers of perception without intervention of the afferent nerves, may produce vertigo. 5. The clinical causes of vertigo have this in common: that they are

capable of interfering directly or indirectly with the cortical function. 6. From experimental and clinical data, vertigo is regarded as essentially a cortical derangement, of either direct or indirect origin. 7. Vivid impressions, particularly those of sound, may inhibit milder forms of rotary vertigo. 8. Impairment of consciousness, caused by the interference with cortical function, is in direct ratio to the severity of the vertigo. From a standpoint of treatment, the author believes that we should use such drugs that will cope directly with the vertigo itself. [F.J.K.]

9.—Houghton advocates the use of animal experiments in determining the dosage of certain drugs, when the chemical active principles can not be isolated. He emphasizes the fact that the strength of certain drugs varies, on account of the different processes of manufacture; also, for the reason that the amount of active constituents contained in the crude drugs varies from season to season, and is modified by habitat, climatic influences, and the method of handling, collecting, storing and curing. [F.J.K.]

10.—Remington states that the decennial convention for the revision of pharmacopeia assembled in Washington on May 2, 1900. Delegates were present from 28 States, representing various medical, pharmaceutical and national organizations, and delegates from the Navy, Army and Marine Hospital Service. Fifty-seven medical colleges and 89 colleges of pharmacy sent delegates. The following officers were elected to preside: President, Dr. Horatio C. Wood, Philadelphia. Vice Presidents, Professors A. B. Prescott, Ann Arbor, Michigan; O. A. Wall, Drs. R. W. Wilcox, New York; N. S. Davis, Jr., Chicago, and A. L. Langfeld, of San Francisco. Secretary, Dr. H. M. Whelpley, St. Louis. Assistant Secretary, Dr. W. G. Motter, District of Columbia, and Treasurer, Wm. M. Mew, of Washington. The Committee on Revision consisted of Charles Rice, of New York, chairman; Dr. H. C. Wood; H. A. Hare; John Marshall; Profs. Remington, Sadtler and Kraemer, of Philadelphia; Drs. J. J. Abel; R. W. Wilcox; Profs. Virgil Coblenz, Gregory, E. H. Squibb, of New York; W. R. Scoville, of Boston; Prof. Caspari and Dr. Dohme, of Baltimore; Drs. N. S. Davis, Jr., W. S. Haines; Profs. Oldberg and Helberg, of Chicago; Prof. Jas. M. Wood, of St. Louis; Dr. George F. Payne, of Atlanta; Prof. Kremers, of Madison, Wisconsin; Prof. L. E. Sayre, of Lawrence, Kansas; Prof. A. B. Stevens, of Ann Arbor, Michigan, and Prof. C. Louis Deal, of Louisville. The author concludes the article by saying that a very successful meeting was held, and that the Pharmacopeia of 1900 will probably appear in three years from now and will receive the same welcome as has been accorded to its predecessors. [F.J.K.]

12.—Weatherson concludes that by his own experimental research he could not confirm the discovery of ureine by Moor. He closely followed the method advanced by Moor; not being successful, he began a series of experiments by more improved methods of research, and finally made investigations to prove that ureine is not a constituent of urine; he was more successful in proving the latter. [F.J.K.]

Wiener klinische Wochenschrift.

February 21, 1901. [14. Jahrg., No. 8]

1. The Question of Phosphorus in Oily Solution. KONRAD STICH.
2. Carcinoma Following Pyloric Ulcer. ANTON KROKIEWICZ.
3. Lipoma of the Small Intestine. ERNST FUCHSIG.

1.—Stich's experiments to decide whether the solution of phosphorus in oil, generally cod liver oil, is really useful or not, are divided into four sections. First.—He found that, with air added, 0.0002 gram of phosphorus is shown by Mitscherlich's method. Secondly.—Weak solutions (1:1000) will keep their phosphorus for some time; but in strong solution (1:100) the phosphorus will diminish, oxidation and the production of yellow phosphorus lowering the strength. To keep phosphorus, it should be dissolved in oil (1:100) and the bottle then filled with carbon dioxide. After cooling, the solution should be diluted 1:1000, and put away in small bottles. These will keep well, and will always be ready for use. Thirdly.—To determine the amount of phosphorus in a given sample of oil containing phosphorus, benzol is added, and the phosphorus precipitated with argentic acetate solution.

The superfluous silver can be withdrawn by the addition of hydrochloric acid. Finally.—When phosphorus in oil is kept in half filled bottles, oxidation will occur, with the production of amorphous phosphorus. [M.O.]

2.—Krokiewicz reports a case of **cancer following gastric ulcer**, in a laborer, aged 34 years. First he had the typical symptoms of pyloric ulcer. Five months later he grew much worse, from which time the cancerous cachexia started increasing till death, after 6 weeks more. His age, the evident connection between the pyloric ulcer and the succeeding carcinoma, the early marked acidity of the gastric contents, with the presence of free hydrochloric acid, and the rapid development of the tumor and its cachexia, all make this case one of great interest. The literature is given. [M.O.]

3.—Fuchs reports an interesting case of **lipoma occurring in the small intestine**, causing invagination, cured by laparotomy. A man, 47 years old, had abdominal pain off and on for a year. Acute attacks of colic then began, with constipation and great distention of the abdomen. Vomiting followed. Laparotomy for invagination was performed 3 days later, showing clear fluid in the peritoneum. All the folds of the intestines were dilated. The invagination was easily reduced, and a tumor, about the size of a walnut, found in the small intestine, which on removal was diagnosed a **submucous lipoma**. The patient recovered slowly. The etiology is unknown. Diagnosis and prognosis depend upon the symptoms of invagination, etc., should they occur. Operation alone will settle this. He cites the literature of the subject. [M.O.]

Deutsche medicinische Wochenschrift.

February 7, 1901. [27. Jahrg., No. 6.]

1. On the Bacteriology of Acute Articular Rheumatism. F. MEYER.
2. A Method for Distinguishing Different Forms of Blood; in Particular for Determining the Presence of Human Blood. H. UHLENHUTH.
3. A Case of Volvulus of the Stomach which had Produced Complete Closure of the Cardia and Pylorus, and Acute Fat Necrosis. WIESINGER.
4. Pathology and Treatment of Cicatricial Contraction of the Bladder.
5. Concerning Some Gouty Phenomena. ADLER.
6. The Bactericidal Action of Light from High Tension Currents, and an Improved Method of Making Use of the Bactericidal Action of Light from the Voltaic Current. H. STREBEL.

1.—Meyer, after having without success investigated the joint exudate in cases of rheumatism, turned his attention to the tonsils and found in the **mucus from the tonsils diplococci** which grew as streptococci, and which produced in animals a peculiar arthritic affection which had close resemblance to rheumatism. The diplococci were very similar to those described by Wassermann, but were apparently not absolutely identical with them. The conclusions which he reaches are, that he was able to find these organisms in the tonsillar mucus in cases of rheumatism, but not in other cases; that they produced a seropurulent, usually sterile, exudate in the joints which did not proceed to sepsis; that the bacteria have a peculiar affinity to the serous membranes and the endocardium in particular, and that this makes it probable that they have a close relation to actual articular rheumatism, but that the number of cases as yet investigated has been too small to allow of any definite decision concerning this matter, and there is as yet no justification for stating whether or not we have in this organism the only cause of rheumatism. [D.L.E.]

2.—Uhlenhuth makes the interesting statement that by **injecting cows' blood into rabbits** at intervals of 6 to 8 days he found that after about 5 injections the serum of the rabbits was found to contain some substance which, when added to a perfectly clear, very dilute, solution of cows' blood, caused a turbidity in this solution. The reaction was found to be absent in experiments on a large series of blood from other animals, and was evidently specific for cows' blood. A similarly specific action was found after injecting various other forms of blood into rabbits, and after injecting human blood the reaction was specific for human blood

alone. The reaction was also observed with human blood that had been dried for weeks and subsequently dissolved in physiological salt solution. Uhlenhuth considers it a specific reaction for various forms of blood. [D.L.E.]

3.—The interesting case occurred in a man of 41, who was taken ill, immediately after a dietetic indiscretion, with the **clinical appearances of intestinal obstruction** associated with enormous distention of the epigastrium and left hypochondrium. There were attempts at vomiting, but nothing was brought forth. The distention increased, and operation was undertaken on the fourth day while the patient was in extremely bad condition. The large mass in the epigastrium proved to be the stomach. It was suspected at first that this was merely pressed forward by a cyst (possibly pancreatic) lying behind the stomach, as the mass felt like a cyst. The stomach was punctured and the contents drawn off, and it was found that the whole mass consisted of the tensely distended stomach. The pancreas itself was found to be normal excepting for perhaps some enlargement. There were widespread areas of fat necrosis. The stomach was found twisted at an angle of about 180° and fixed in this position. The cardia and pylorus were completely closed. There was beginning peritonitis. The stomach was replaced in proper position, and the wound closed. The patient recovered completely, and had subsequently no digestive disturbances. The case was notable for the complete cure of the fat necrosis. The latter condition was probably due to pressure upon the pancreas by the enormously distended stomach. The occurrence of volvulus of the stomach was attributed to the displacement of the colon above the stomach resulting to the abnormal length of the mesocolon; after a partial volvulus had occurred this was increased by the enormous secretion which took place in the stomach. [D.L.E.]

5.—Adler makes some remarks on gout, based upon pure theory. He thinks that the **reason the deposits occur** in the cartilages about the joints is due less to the fact that the circulation is poor than to the tendency that cartilages have to attract deposits. They normally attract a deposit of calcium salts, and Adler thinks this natural tendency is also exerted upon uric acid. He considers that perhaps diarrhea, the free secretion of saliva seen in gout, may be due to an effort to rid the blood of an excess of uric acid. [D.L.E.]

6.—Strebel presents reasons for believing that only the ultraviolet rays and the rays beyond kill bacteria, and that it is the invisible rays that are chiefly active. He describes various experiments which he has carried out with the ultraviolet rays, using various lenses. [D.L.E.]

Münchener medicinische Wochenschrift.

1.—Bonhoff reports the case of a woman, 57 years of age, who was attacked with sudden pain in the back of the head. She became delirious, had fever, and retraction in the neck. A lumbar puncture showed the presence of pus cells and bacteria in the fluid. The patient died, and at the autopsy there was found that aside from a very slight congestion, the membranes of the brain were normal, but there was a considerable amount of yellowish-green turbid fluid in the membranes of the cord, and a grayish-green infiltration of the pia about 2 mm. in thickness. It is interesting to note that there were no other cases in the patient's neighborhood either before or after her sickness. Cultures upon Löffler's blood

serum caused a growth of typical *meningococci*. These Bonhoff believes to be perfectly distinct from other forms, partly by their morphological and cultural peculiarities, and partly by their very limited pathogenicity. They have a very slight effect upon guineapigs, kill mice very readily, and it is practically impossible to immunize rabbits, although in those animals to whom ascending doses of the cultures were given, some protective power existed in the blood-serum. In addition, a peculiar bacillus was found, which occurred quite frequently in the cultures, and somewhat resembled the one described by Stadelmann. This appeared first on the fifth day, but later appeared 48 hours after reinoculation. They are non-motile, and do not ferment grape sugar. Although he is not certain that they are the same as Stadelmann's bacillus, he regards them as a form of pseudo diphtheria bacillus that has no influence upon the disease. [J.S.]

2.—Kuhn calls attention to the great importance of securing free openings in all operations for the removal of gallstones. He mentions a case in which the patient was apparently relieved, but at the second operation the gallbladder was found filled with clear bile, and a single faceted stone, evidently overlooked at the previous operation, blocked the opening of the cystic duct. He also mentions another case in which only after prolonged palpation a similar concrement lying in the neighborhood of the duodenum and completely blocking the duct was found. Finally he describes the case of a woman in whom a permanent biliary fistula occurred as a result of adhesion of the connective tissue bands including the common duct. At the third operation it was found that there was stenosis at the pylorus, and a fistula between the gallbladder and the duodenum was made, as a result of which the patient readily recovered. In these cases he used a spiral sound having a bulbous extremity with great success. [J.S.]

3.—Jordan reports the case of an officer, 23 years of age, who was thrown from his horse and received a severe blow in the left side from the handle of his sword. There was immediate, intense pain and a feeling of weakness, requiring his immediate removal to the hospital. Here he was seized with vomiting, progressive collapse, severe anemia, and contraction of the muscles of the abdomen. As these indicated internal hemorrhage, it was decided to perform immediate laparotomy, when a considerable effusion of blood was found in the peritoneal cavity, evidently a result of a **rupture of the spleen**, from which blood was still pouring. The spleen was, therefore, extirpated, and the wound closed. It was noted that part of the intestines were still in a state of spasm as a result of the injury. In the course of 2 months the patient had recovered sufficiently to leave the hospital, and undertake a bath-cure. Four months after the injury the leukocytes were slightly increased, the hemoglobin and red blood-cells, slightly decreased. There were no evidences during recovery of vicarious hypertrophy of the lymph-glands or the bone marrow. Examination of the spleen showed that the rupture had occurred upon the concave side. One hundred and thirty-five cases of this injury are on record, with the following results: 5 healed spontaneously; 16 were saved by extirpation of the spleen; and 104 died. Of these, 3 died from abscess, and the rest from hemorrhage. Jordan draws the conclusion that, if after severe secondary anemia produced by hemorrhage, a man can recover almost completely, although his spleen has been removed, it is not likely that this organ is of great importance in the formation of blood. [J.S.]

4.—Gossner reports the case of a man who attempted suicide by starvation. At the end of the twelfth day pain drove him from his place of concealment and he was carried to the hospital unconscious. Both legs became gangrenous and were amputated above the ankles. The stumps suppurated, and some months later another amputation was performed, without forming any periosteal flaps. Suppuration again occurred in the stumps, but gradually the surface granulated and healed, and the patient was able to walk without support of any kind, and even to go up and down stairs. Gossner reports the case as an illustration of the hopefulness of amputation through the legs, in spite of the most untoward complications. [J.S.]

5.—Schlesinger reports 2 cases of **pseudo-membranous conjunctivitis**. In the first case diphtheria bacilli were not obtained in the cultures; nevertheless, an injection of antitoxic serum was given, and in addition vigorous local

therapy with antiseptic solutions was employed. The patient recovered completely. In the second case numerous diphtheria bacilli were found. The same treatment was employed, and the results were again excellent. The advantage in the employment of the antiphtheritic serum was that it hastens the separation of the membrane, as well as that it improves the general condition of the patient. It should be used in this condition, as in all others, at the earliest possible moment. [J.S.]

6.—See editorial.

7.—The difficulty of the **filtration of agar** has caused many ingenious schemes to be devised, the majority of which depend either upon using pressure or suction force, or the employment of some filtering substance with larger pores. A few have endeavored by various means to render the agar solution more fluid. To the second group belongs the method of Paul. It occurred to him that sand, on account of the fixity of the size of its pores, would probably be a most desirable substance. His apparatus consists of 2 vessels, one containing a perforated bottom resting upon the rim of the other. The sand, of course, is placed in the upper one, a layer of gauze retaining it in position. The arrangement is rather peculiar. There is first a layer of large pebbles 3 cm. in thickness, then one of small pebbles, 2 cm. in thickness, then 6 cm. of sand, and the 2 layers of pebbles in inverse order. Each layer is separated by gauze. The filter is first thoroughly washed with boiling water, is then placed in an ordinary steam sterilizer and heated until it reaches 100° throughout. The agar is then poured upon it and filtration commences. With this apparatus Paul has filtered 30 litres of agar in 2 hours, and the amount of loss is very slight. [J.S.]

8.—Bade believes that a properly fitting **corset** exercises a favorable influence upon the course of **tabes dorsalis**; why, he is not clear. The corset, as usually prepared, has certain unpleasant features, particularly the supports of the arms, and the portions over the hips. Unless these fit exactly they cause great discomfort and often the formation of serious sores. All these disadvantages Bade has endeavored to overcome by the employment of a corset made of leather, carefully fitted so that it rests firmly upon the hips. There is also a special band made for the waist, which binds firmly the upper and lower portions of the corset together, and enables the body to move freely at this point. A partial support is given to the back by springs. [J.S.]

9.—Wiesner describes the Röntgen-ray apparatus of Des-sauer, which is distinguished for its simplicity and effectiveness. The reproductions of the pictures that have been taken with it have, unfortunately, been omitted. [They are given in the following number. J.S.]

Berliner klinische Wochenschrift.

February 4, 1901. [38. Jahrg., No. 5.]

1. Fatigue and Recreation. M. VERWORN.
2. Observations on the Treatment of Puerperal Fever with Marmorek's Antistreptococcus Serum. M. BLUMBERG.
3. A Case of Hysterical Sensory Aphasia in a Child. L. MANN.
4. Hygiene of the Eye in the Nineteenth Century. H. COHN.

2.—Will be abstracted when concluded.

3.—Mann reports a case of **hysterical sensory aphasia** occurring in a girl 7 years of age, with negative family and personal history. It was elicited, however, that within 2 days previous to the onset of the affection the child had become vexed and cried considerably. The mother stated that for 4 weeks she had noticed that the child had been speaking indistinctly, and this progressed so rapidly that within 3 days the child's utterances became unintelligible. According to the mother the child became at the same time completely deaf. The author upon examination coincided with the physicians who had previously examined the patient, namely, that the child was completely **deaf**. She would not respond when addressed, no matter how loud she was spoken to, peered into vacancy or shook her head, at the same time speaking unintelligently in a manner that seemed to indicate that she did not understand. A noticeable feature, however, was the intelligent, attentive, and interested expression, and also, according to the mother, there seemed to have been no diminution

in the intelligence of the child while performing her daily duties. After a few days, when the confidence of the child was obtained, the author found that no real deafness was present, but that the child was unable to understand spoken words, and that the perception of ordinary noises was fully preserved, it being, therefore, a condition of so-called "word deafness" or sensory aphasia. In the absence of other cerebral symptoms and on account of the peculiarities of those present the author believes that this was an hysterical manifestation with a not yet described symptom-complex. Upon isolation, painful faradization and systematic practice in articulation, improvement soon set in with complete recovery. The persistent suggestive treatment applied for some time before a result was obtained, seems to indicate that an isolated symptom of hysteria may persist for some time, to ultimately disappear under suggestive treatment. [M.R.D.]

4.—Cohn reviews the hygiene of the eye in the nineteenth century and could not find anything in literature before 1800 on the subject, with the exception of Bartisch's work which contains a few facts that are recognized even at the present time. All the years of consequence in ophthalmic hygiene are considered *seriatim*. [M.R.D.]

Centralblatt für Gynäkologie.

1. The Prevention of Purulent Inflammation of the Eyes in Newborn Children. P. ZWEIFEL.
2. Test of Lysoform as a Method of Hand-Disinfection. F. AHLFELD.
3. Gangrene of the Lower Extremities in the Puerperium. GEORGE BURCKHARD.

1.—Zweifel presents an exhaustive paper upon the **prophylaxis of purulent inflammation of the eyes in newborn children**, with especial reference to Credé's treatment by silver nitrate solution, 2%, and the more recent silver salts which have been employed in this disease. He draws attention to the difference experienced between patients as met with in clinics and in private practice, the greater number of cases occurring in children delivered by midwives. He agrees with the other obstetricians in attributing the vast majority of cases of the ophthalmia of the newborn children to Neisser's gonococcus. The secret of the prevention consists in an immediate cleansing of the eyes after birth with sterile water followed by the instillation of the remedy that is to be employed. He remarks that in a number of these cases the lochial secretion will not show the characteristic gonococci, but every mother whose vaginal secretion appears in the slightest degree suspicious should be placed on prophylactic douches and the eyes of the child be treated in the manner mentioned. For some years Zweifel had employed a 3% solution of boric acid as an eye-wash and had obtained very satisfactory results. In another group of cases he employed a 1% solution of formalin, one drop being instilled into each eye at birth; of 120 children so treated, but 4 presented inflammatory changes in the eyes, that is 3.3%. Since 1895 the newer silver salts have been employed, also such solutions as salicylic acid by Bischoff, chlorin-water by Schmidt-Rimpler, thymol by Schirmer, boric acid by Credé-Wecker, potassium permanganate by Valenta, and carbolic acid, mercuric chlorid, and sulpho-carbolic acid of zinc. Olshausen while using a 1% solution of carbolic acid had 8% of ophthalmia; with the 2% solution he had but 3% of ophthalmia. Späth with 1% carbolic acid had 1.4% of ophthalmia, while Krukenberg with a 2% solution had 13.4% of ophthalmia. Schröder with a sublimate solution had from 4% to 6% ophthalmia and with sulpho-carbolic acid of zinc he had but 3% ophthalmia; finally Erdberg with a 1 to 7000 sublimate solution had but 4% of ophthalmia. The acetate of silver has been employed with boiled water with comparatively satisfactory results, as has also silver nitrate; thus he treated 43 children with this salt and had but two cases of ophthalmia, or 4.6%. Zweifel gives the results of some experiments which were made by him with these newer preparations. [W.A.N.D.]

2.—Ahlfeld has instituted a series of experiments upon **disinfection of the hands by lysoform**. Eighteen of his pupils have repeatedly made use of this substance, 6 with

a 3% solution and 12 with a 4% solution. The entire 18 have primarily employed the usual methods of cleansing the hand followed by the use of hot water, soap and brush for 5 minutes. The lysoform is then rubbed in with a brush for 5 minutes, after which the hands are immersed in sterile warm water. Notwithstanding this thorough testing, Ahlfeld is inclined to believe that the method is no better than the methods usually employed, although the germs are destroyed probably as well as by the methods generally recommended. [W.A.N.D.]

3.—Burckhard has been able to collect from literature 14 cases of **gangrene of the lower extremities during the puerperium**. He reports 2 cases which have come under his own observation. The first patient, 38 years of age, passed through a difficult birth at the end of the seventh pregnancy, the child occupying a transverse position. Examination showed that the lower uterine segment was considerably distended and uterine rupture threatened. The right shoulder lay deep within the pelvis, while the right arm of the child had prolapsed and protruded in a deeply cyanosed condition from the pelvis. The back of the child was directed posteriorly while the head projected over the symphysis. Decapitation was performed by Braun's hook and after the extraction of the child there was a profuse hemorrhage from the placental site. An incomplete uterine rupture was found on the left side, the hemorrhage from which was arrested by means of an intrauterine tamponade. The puerperium was practically normal until the twelfth day, when the temperature arose and the toes of the left foot became anesthetic. The latter condition steadily progressed up the foot to the ankle and gangrene began, which necessitated an amputation after the method of Grritti. Examination showed that the popliteal vein had been thrombosed. The second patient was 32 years old in her fifth labor. Kolpurysis was employed and the child extracted by version. The maternal pelvis was flattened and the child, which was stillborn, presented a spoon-shaped depression on the right parietal bone. On the second day of the puerperium the patient experienced severe pain from the symphysis down the left limb; the foot became cyanotic and anesthetic, a line of demarkation formed across the malleoli, and amputation was required of the left leg in its upper third. Examination showed that thrombosis of the posterior tibial artery had occurred. Burckhard remarks that in the 17 cases of this complication collected from literature endocarditis was observed twice. [W.A.N.D.]

Centralblatt für innere Medicin.

January 12, 1901. [25. Jahrg., No. 2.]

1. Concerning the Influence of Morphia upon the Stomach. ALFRED HIRSCH.
2. The Effect of Thyroidin Preparations in Certain Rare Cases. ARTHUR JAENICKE.

1.—Hirsch found that the **subcutaneous injection of 1 cg. of morphia per kilo of body-weight in dogs resulted in the complete retention of fluids in the stomach**, while under normal circumstances these left the organ within an hour and a quarter. The secretion of HCl continued. The expulsion of the fluid was still markedly decreased 10 or 11 hours after the injection, while the secretion of HCl had much increased. While listening over the stomach it was found that there was a loud noise in the region of the pylorus similar to that made when the pyloric portion of the stomach is attempting to drive air or fluid through the pylorus. This indicated peristalsis of the stomach, but since, in spite of this marked activity of peristalsis, no gas or fluid escaped, it seemed evident that the cause of the condition was a tonic contraction of the pylorus producing temporary obstruction. The fundus of the stomach seemed to remain quiet. The condition of the pylorus and the marked increase of the peristalsis were considered to be due to excitation of the contraction centers per the pylorus and pars pylorica in the corpora quadrigemina. The HCl secretion was decreased in the beginning, probably from the fact that the morphia injected subcutaneously is excreted by the gastric mucosa. The subsequent hypersecretion was thought to have a central origin. The results, then, of morphia injection were to produce difficulty in emptying

the stomach; first a decrease and then a marked increase in the HCl; the influence of the drug increased progressively with increase in the dose; the use of the drug subcutaneously produced more marked effects than use by the mouth. As to atropin he found that it produced less marked but still notable disturbance of expulsion which lasted for at least 6 hours. HCl was completely absent during the first hour, but was again normal after 6 hours. There was at the latter period a marked flow of bile which is never observed after morphia. Hirsch also observed in narcotizing a dog with ether that the ether and morphia seemed to act antagonistically.

2.—The first case described was that of a woman who had a **mammary tumor** which was at first thought to be malignant. Thyroidin was given and there was a rapid decrease in the size of the tumor, and it ultimately practically disappeared. Similar effects were observed in 2 cases in which there were **large lymphomata**, and also in 3 cases of marked **splenic enlargement** without increase of leukocytes. The histories are given somewhat in detail. It is noted that one patient took within 6 years more than 4,000 tablets, containing 5 grains each, of thyroidin, without bad effects. [D L E]

1. The Participation of the Spleen in the Formation of the Albumin Ferment of the Pancreas. A. A. GERTSEN.
2. On Writer's Cramps. I. W. ZABLUDOWSKY.
3. The Diagnostic and Prophylactic Significance of Koch's Tuberculin. PH. A. DOMBROWSKY.
4. Electrolysis in Cicatricial Stricture of the Esophagus. N. W. SLETOW and P. I. POSTNIKOW.

1.—Gertsen devotes his paper to a critical reply to Dr. Popelsky, who published in the *Vratch* of 1899, No. 25, the results of some of his experiments intended to disprove the assertions of Shiff, Pachon and the author to the effect that the spleen is intimately associated in the formation of trypsin from protrypsin. The author, who has done considerable experimental work on the subject, finds no difficulty in showing that not only were the experiments of Popelsky useless but that they actually establish the very facts against which they were directed. Gertsen's contentions are: 1. The amount of trypsin in the pancreatic juice or an infusion of the pancreas is proportionate to the swelling of the spleen which takes place at the height of digestion. 2. In dogs and cats, receiving their food only once in 24 hours, the swelling of the spleen and the increased formation of trypsin begin simultaneously five hours after the ingestion of food, reaching the maximum at the seventh hour, when they disappear gradually. 3. Animals from which the spleen has been removed not only do not show such increase in the secretion of trypsin, but the latter disappears entirely from the pancreatic juice or an infusion of the pancreas. 4. By adding to a solution of trypsin, *i. e.*, an infusion of the pancreas in a state of rest, an equal quantity of an extract of spleen in a state of physiologic activity, the protrypsin is at once converted into active trypsin. 5. The same results are obtained with the venous blood of the swollen spleen. 6. If half of the pancreas be removed from a dog from which the spleen had been removed, and an intravenous injection made of a watery extract of a swollen spleen, *i. e.*, one removed at the height of digestive activity, and 20 minutes later the second half of the pancreas be removed, an infusion of the first half will not digest any albumin while the second half will show great digestive powers. These claims are substantiated by a considerable number of careful experiments, some of which are described by the author. [A. R.]

2.—Will be abstracted when completed.

3.—Dombrowsky has employed Koch's tuberculin for diagnostic purposes with very satisfactory results. The reaction when present was always marked, the temperature-elevation varying from 0.7 to 1.5 C. Of 12 patients 3 reacted after the first, 6 after the second and 3 after the third injection. No albuminuria or diazo-reaction followed. The method employed by the author is one described by Fränkel and is essentially as follows: 0.1 c.c. of tuberculin is mixed with 10 c.c. of sterile water. Of this mixture one division of a Pravaz syringe, *i. e.*, 0.1 c.c. of the mixture, or 0.001 of

tuberculin, is injected subcutaneously. If no reaction takes place the injection is repeated on the third day, increasing the dose to five divisions of the syringe or 0.5 c.c.; if still no reaction follows the entire contents of the syringe, or 0.01 of tuberculin, are injected. The reaction is considered positive when the elevation of temperature reaches at least 0.5 C. Both prior and after the injection the temperature is taken every three hours, except between 9 in the evening and 6 in the morning, for three consecutive days. The prophylactic value of the tuberculin test the author sees in the early recognition of the disease afforded by it. A claim for its perfect harmlessness is made. [A. R.]

4.—Sletow and Postnikow treated successfully by electrolysis two severe cases of stricture of the esophagus, resulting from taking ammonia. The diagnosis was established beyond doubt by several specialists, and the various mechanical means employed to dilate the stricture resulted in failure. The authors achieved success promptly by means of olive shaped electrodes introduced into the esophagus, using a current of 5 to 10 m.a. for 1 to 5 minutes. The beneficial effects of electricity in such cases the authors explain by the theory that the current, coming in contact with the cicatrix, produces certain chemical changes which soften and dissolve the new-formed tissue. The assertion of some authorities that the effect is due to cauterization is proven to be erroneous by a simple mathematical calculation of the thermic value of the current as well as by the fact that the electrode is practically cold when removed. The authors prefer an olive-shaped electrode, as it is much more certain to come in intimate contact with the cicatricial tissue. This should be made of brass, nickel or silver plate, $\frac{1}{2}$ to 2 c.m. in diameter. The method employed is described, but does not differ essentially from those generally practised. [A. R.]

3. On the Question of Determining the Oxidizability of Water by Means of Permanganate of Potash. A. PH. DRSHEWETSKY.
4. On Writer's Cramps. I. W. ZABLUDOWSKY.

1.—Considered editorially.

2.—Will be abstracted when completed.

3.—Will be abstracted when completed.

4.—Zabludowsky devotes an exhaustive paper to the subject of the etiology and treatment of writer's cramp. He deprecates the indiscriminate use of the term, irrespective of the cause or extent of the abnormality present. Many of the so-called cures may be ascribed to the laxity of nomenclature. He divides the affection into the following forms: 1. Ascending form, due to diseased conditions of the muscles and nerves of the upper extremity. Under this heading he considers (a) Paralytic manifestations, such as partial or complete paralysis; (b) inflammatory conditions, such as neuritis, neuralgia, and myositis; (c) tremor; and (d) spasms. 2. Descending form, brought about by diseases of the central nervous system, such as apoplexy, tabes, unilateral degenerations of the spinal cord. 3. Disturbances of the central nervous system produced by such conditions as hysteria, neurasthenia, Graves' disease, senile degenerations, and cardiac diseases. 4. Mixed forms. In making a diagnosis, the patient should be subjected to a careful physical examination to ascertain the cause. He is then told to write in the presence of the physician, as well as bring several specimens of his writing done at home under more favorable circumstances. The treatment and prognosis vary, of course, with the form of the affection. Generally, however, it resolves itself into writing exercises, massage, Swedish movements, and in the correction of any faulty habits of writing, such as improper position, manner of holding the pen, etc. In the graver forms the use of mechanical appliances intended to relieve the strain on the digital muscles or do away altogether with the use of the fingers is to be recommended. The employment of the typewriter is advisable, especially since it affords a gentle exercise to the fingers. As a prophylaxis, the author lays stress on the proper position to be assumed while writing, and other details pertaining to calligraphic hygiene. [A. R.]

Original Articles.

THE TOXICOLOGY OF TELLURIUM COMPOUNDS, WITH
SOME NOTES ON THE THERAPEUTIC VALUE OF
TELLURATES.By WILLIAM J. GIES, M.S., PH.D.,
of New York.

Instructor of Physiological Chemistry, Columbia University.

A. Action on Plants and Microorganisms.—The earliest as well as most important researches on the biological influence of tellurium compounds were conducted on domestic animals and on man. It was not until 1885 that the results of a study of their action on plants was announced. Knop, in that year, after an investigation of the influence of various substances on growing plants (maize) by the water-culture method, reported that telluric acid¹ to the amount of 0.05 to 0.1 gm. per litre of nutrient fluid, (0.005–0.01%), exerted no observable influence on their development, although analysis of the plants showed that tellurium had been absorbed.

Bokorny, a few years later, working with tellurous oxide and potassium tellurite, found that aqueous solutions containing only a trace of the very insoluble oxide had no effect whatever on algae and infusoria, even after 5 days' treatment, and that 0.02% solutions of potassium tellurite (containing, also, 0.1% of dipotassium phosphate) were likewise without toxic influence, although the algae had been kept in the fluid for a week. Under the microscope the cells were seen to be perfectly normal in all outward aspects. Even with a 0.1% solution of potassium tellurite (containing a trace of potassium hydroxide), only one form of spirogyra seemed to be affected. All of the rest vegetated normally, even at the end of a week of treatment. Continuing his experiments, Bokorny, in the following year, reported that when various algae, such as *Spirogyra communis*, *S. nitida*, *conferveae*, *diatomaceae*, etc., and also infusoria, were placed in 0.1% solution of telluric acid and kept there in diffused light for some time, little, if any, influence was exerted. At the end of 48 hours the Algae remained perfectly normal, and the infusoria swam about in very lively fashion. Even after 14 days some of the algae were still growing, in spite of the fact that the faintly acid solution contained no mineral or other nutrient material. Potassium tellurate (slightly alkaline in reaction), in like quantity, was just as innocuous.²

Scheurlen, very recently, wishing to grow *bacillus anthracis* in pure cultures, and in the absence of atmospheric oxygen, sought a medium which, containing loosely bound oxygen in oxyhemoglobin-like combina-

tion, would be almost as favorable to their growth as blood itself. Having previously found that selenious acid on warming with organic substances is reduced and red selenium deposited, he experimented with sodium selenite and also with sodium tellurite, which on similar treatment yields grayish black metallic tellurium. He found that not only *B. anthracis* but also all of the growing bacteria he worked with were colored by reduced metal in the presence of sodium salts of these acids. The bacteria themselves were colored, not the nutrient medium. They were grown on 10 cc. of a meat infusion peptone agar with 1 to 3 loopfuls of a 2% solution of the salts.

These results led directly to the detailed work conducted by Klett, who studied the growth of numerous species of bacteria and some moulds under the influence of selenium and tellurium compounds, and found that the development of various forms, such as *staphylococcus pyogenes aureus* and *B. mesentericus vulgaris*, as well as the various moulds, was not materially hindered by slight quantities of sodium tellurite, although several others, such as *B. fluorescens liquefaciens*, were strongly retarded in growth by only traces of the tellurite, which seems to be more inhibitory than the selenite. Yet a few, such as the bacillus of malignant edema and of symptomatic anthrax, which are markedly arrested in growth by selenite, not only reduce tellurite, but appear to continue their development in the presence of a larger proportion of the latter salt. Most of the experiments were made on 10 to 12 cc. of nutrient medium (gelatin, agar-agar), containing 1 to 3 loopfuls of 2% solution of the tellurite. Increasing amounts of tellurite wrought more destructive effects, of course. The colonies in all cases, as in Scheurlen's experiments, were colored grayish black by metallic tellurium, the intensity of the coloration having been proportional to growth. Grayish particles were deposited within the bacteria. Since the colonies only were pigmented by the metal and the surrounding medium was left entirely colorless, Klett concluded that the reduction took place in the protoplasm of the bacterial cell and not outside the cell by secondary action of metabolic products. For this reason, then, he considers tellurites, with selenites, the most satisfactory reagents for detecting and determining accurately reducing action on the part of bacteria. It was observed, further, that the oxygen set free from tellurite during the reduction could not be utilized by aerobic bacteria in anaerobic environment, nor was the presence of tellurite favorable to the growth of anaerobic forms. Klett found, also, that tellurite, in the quantities used, did not decrease the virulence of such forms as *B. anthracis*. Sodium tellurite was the only tellurium compound tried in this connection. Sodium selenate in slight quantity was found to have little or no effect on the growth of bacteria and was not reduced. Klett appears to have concluded, from analogy, that tellurates, also, would not be reduced by them.³

B. Effect on the Human Body.—Chr. Gmelin appears to have been the first to give special attention to the action of tellurium compounds in the animal body. Early in the last century he experimented with tellurous acid on a dog and a rabbit. The former he gave 3 grains (0.2 gram) in a single dose; the latter, 14 grains (0.9 gram) in the course of three days. The dog lost its sprightliness at first and

¹ Tellurium was discovered in 1782 by Müller von Reichenstein, and identified and named (from *tellus*, the earth) by Klaproth in 1798. The metal is silver-white of lustrous crystalline structure, with strong metallic lustre. Its atomic weight is still uncertain, but it is estimated at 127. Tellurium is very nearly related chemically to sulphur and selenium. Its chemical qualities have been studied the most problematically in the numerous discovery, and at first it was designated as *paradoxum* and *metallum problematicum*. It is one of the rarer elements and occurs in nature mostly as telluride in combination with bismuth, lead, mercury, silver, and gold. The following formulae show the composition and relationships of the tellurium compounds referred to in this paper:

Tellurous oxide	TeO ₂
Telluric oxide	TeO ₃
Tellurous acid	H ₂ TeO ₃
Telluric acid	H ₂ TeO ₄
Sodium tellurite	Na ₂ TeO ₃
Sodium tellurate	Na ₂ TeO ₄
Hydrogen telluride	H ₂ Te
Methyl telluride	(CH ₃) ₂ Te
Ethyl telluride	(C ₂ H ₅) ₂ Te
Potassium tellurate	K ₂ TeO ₄

² Further reference to effects on lower animals is made farther on in the reviews of Hofmeister's and Czapek and Weil's work.

³ The author is greatly indebted to Dr. P. H. Hiss for the references to the work of Scheurlen and Klett, and for suggestions to connect it with this review of their results.

also its appetite, but in a few days recovered both. The rabbit's appetite remained normal throughout the experiment, but on the fourth day it died. On post-mortem examination of the poisoned animals Gmelin noted that a peculiar garlicky odor proceeded from the abdominal cavity; that the mucous membrane of the stomach and intestines was much swollen and covered with a thick layer of tough mucus; and that from the pylorus to the rectum the walls of the intestines were very black. The liver was covered with minute red spots, the blood-serum colored violet, the gallbladder widely distended and the heart full of coagulum.

A more extended series of experiments was next carried out by Hansen, who, working in Wöhler's laboratory, found that 0.3 gm. of potassium tellurite, introduced directly into the stomach of a medium-sized dog, was followed almost immediately by an unpleasant, garlicky odor in the breath, similar to that which Gmelin had noted on opening the bodies of the poisoned animals and which Wöhler and his pupils had attributed to ethyl telluride. Twenty minutes after dosage repeated vomiting ensued. The symptoms noted by Gmelin (languor and loss of appetite) were also observed and recovery was not long delayed. The same dose twice on the following days, morning and afternoon, induced identical results, while the odor in the breath became stronger each day and persisted long after the conclusion of the experiment. The vomit and feces were slimy and black with tellurium granules.

In a second experiment on a dog of average size, 0.5 gm. of tellurous acid *per os* on two succeeding days caused no toxic symptoms, although the odor of the breath became more and more marked, and the feces were blackened by metallic tellurium. On the third day, 0.7 gm. of acid potassium tellurite induced vomiting of grayish-black slimy material in addition to the previous results, and the odor of the breath rapidly grew stronger. On the fourth day another dose of 0.7 gm. of the tellurite caused vomiting, and considerable thick mucus ran from the mouth. On the seventh day 0.5 gm. of the same potassium salt, in solution, was injected into the jugular vein. Convulsions resulted at once and death followed in four minutes. The body cavity gave off the characteristic odor and the alimentary tract as well as the kidneys and all other glands, except the spleen and parotids, were colored bluish-black. The liver was not covered with the inflammatory spots, nor was the blood-serum colored violet, as Gmelin had previously found. The lungs, brain and spinal cord retained their normal appearance. The pigmentation of the glands, etc., was caused by deposition of microscopic granules which were shown to consist of tellurium. The peritoneal cavity contained a small quantity of serous fluid, but neither hyperemia nor inflammation was observed. The wall of the urinary bladder was bluish in color and the urine, acid in reaction, contained the odoriferous compound. The right side of the heart and the vena cavae were swollen with blood. In the crystalline lens of each eye, as reported by Hansen's friend, Dr. Schrader, there was a deposit of chalky granules of varying size. They were least in quantity in the center. The cataract was greatest in the left eye. The humours of the eye gave off the odor of garlic. Tellurium was separated from the urine, liver, stomach and intestines. Two additional experiments on dogs gave results that were identical with the above in practically all particulars. The blood-serum was normal in color in each case.

Hansen concluded his paper with the opinion that the pigmentation of the contents of the gastrointestinal tract was due to deposition of tellurium by a process of reduction and that direct absorption of the metal through the intestinal wall was indicated by the bluish-black color of the mucous membrane. He suggested, further, that the violet color of the blood-serum, noted by Gmelin, was due to the presence of absorbed metal in suspension, and that it was not observed in his own experiments because there had been time in each for the tellurium to be deposited in the tissues.

Kletzinsky,⁴ also, in experiments on animals noted that administered tellurium was eliminated, in part, in the urine. Rabuteau, 15 years after Hansen's results had been recorded, found tellurium to be exceedingly poisonous and considered it very similar in its action to selenium, although stronger. This deduction was based on the results of only one experiment, however, with sodium tellurite. Following an intravenous injection of 0.08 gram of that substance in a dog, vomiting ensued within 2 hours, after which profound dyspnea set in, with anesthesia, opisthotonus, and finally death from asphyxia in 4 hours. Postmortem examination 12 hours after death showed marked congestion and ecchymosis of the whole of the intestinal canal; also of the liver, spleen, lungs and especially the kidneys. The latter were almost black as a consequence and the tubuli were studded with fat globules. In the heart the right side was filled with blood, the left side on the contrary was empty.

The contents of the right side of the heart, and also of the larger bloodvessels, held a multitude of small prismatic crystals of unknown chemical composition—0.002 to 0.004 mm. in width and from 5 to 10 times as long—which, in the opinion of Rabuteau, presented a mechanical obstacle to the movement of the blood and thus eventually caused the death of the animal in asphyxia. These crystals were apparently identical with those Rabuteau reported he had found under similar conditions after intravenous injections of sodium selenite and administrations of the same *per os*. They were not produced, he says, by selenates—only by selenites and tellurites. Rabuteau states, further, that they were more numerous than the corpuscles. He says nothing about their color, but his sketch of them suggests that they may have been hemoglobin or some derivative of it. Radziejewski⁵ seems to entertain this opinion.

It should be remarked, in passing, that Chabrie⁶ and Lapique⁷ were unable to find these crystals in the blood of animals poisoned with sodium selenite and, also, that Czapiek and Weil, whose work with tellurium is summarized farther on, obtained the same negative result, both with selenites and tellurites, after intravenous injections. Rabuteau's observations in this connection have never been confirmed. Consequently, his theory that death after injection of tellurites results from a "mechanical poisoning," which produces asphyxia, cannot be accepted. Rabuteau makes no reference whatever to the work of Hansen, or any of his predecessors, and says nothing definite about odor in the expired air of the dog to which he had given tellurite.⁷

⁷ The odor caused by selenites Rabuteau mistakenly ascribed to hydrogen selenide instead of methyl selenide. He mentions, where extraneous facts are referred to on a subsequent page, assumes that the odor was hydrogen selenide by Rabuteau, and, from analogy apparently, that it was referred in error to hydrogen telluride.

Czapek and Weil, in perhaps a more thorough research than any of the preceding, learned that, in its toxicological influence, tellurium behaves very much as does its close chemical relative, selenium, although the symptoms it induces appear later and are, for the most part, weaker—just the reverse, in the latter respect, of Rabuteau's deduction. Sodium tellurite, in quantities of 0.002 gm., under the skin, caused the death of frogs within 48 hours; 0.01 gm. of sodium tellurate was required to produce the same result. In cold-blooded animals these quantities of tellurium gradually brought about paralysis of the central nervous system and death. The heart was arrested in diastole, apparently because of paralysis of the so-called excito-motor ganglia. Atropin did not restore the beats, and the heart-tissue itself remained susceptible to mechanical and electrical stimulation. The garlic odor was detected about the animal in most of these cases. Muscular fibrillations were almost always observed in frogs into which tellurium had been injected, but neither clonic nor tetanic convulsions followed its introduction in the quantities employed.

In warm-blooded animals these same observers found that 0.02 gm. of sodium tellurite, and 0.05 gm. of sodium tellurate, per kilo of body-weight, gave very toxic effects.⁸ Dogs very soon became restless. Vomiting quickly ensued, followed by diarrhea, weakening of the reflexes, somnolence, unconsciousness, general paralysis, stoppage of respiration, and death after convulsions. Within five minutes of the time of administration of the poison, the garlic odor in the expired air was intense. There was no muscular fibrillation as in the case of frogs, and, with the exception of the spasm just before death, no clonic or tetanic convulsions. In all cases a lowering of blood-pressure followed the injection of tellurium salts. This was due, not to central influences, but to direct peripheral action on the blood-vessels, resulting in impaired tonic contraction, for the vasomotor center remained sensitive to stimulation and the vagi were able to carry impulses. The abdominal capillaries, particularly, were very greatly distended.

The blood from animals poisoned with tellurium was dark-colored and had a distinct garlic odor. Spectroscopically it was normal and the corpuscles showed no change. Czapek and Weil could not confirm Rabuteau's observation in this connection. Postmortem examination showed profound changes in the intestinal mucous membrane, in which edema, congestion, and extravasations were especially prominent. Desquamation of the villi was also observed in most cases. Destructive changes were the rule in the tubules of the kidneys. The urine was bloody now and then, and frequently tellurium could be detected in it. Nearly all of the body parts, in the cold as well as warm-blooded animals experimented on, were colored grayish by metallic tellurium, but no deposit of the metal in granules was observed, on microscopic examination, in any of the tissues. It seemed to be in solution. The muscles of the poisoned animals retained their susceptibility to stimulation.

Tellurium was found to differ from selenium, in toxicity, mainly quantitatively.⁹ Czapek and Weil concluded that the difference between the two lies in the different modes of elimination. Tellurium salts are less toxic, they think, because the tellurium is quickly transformed by

reduction to the metallic state and so is rendered comparatively passive at once. The results of their experiments indicate that in its toxic action tellurium behaves much as do selenium, arsenic and antimony.¹⁰

Although the garlic odor in the breath and about the organs of animals to which tellurium salts had been administered was thought at first to be due to ethyl telluride, its resemblance to methyl telluride, when that substance was first made, satisfied Wöhler and his pupils that it resulted from a formation of that organic compound. This conclusion was generally accepted for some time. Hofmeister, in some very exact experiments, finally determined in a chemical way that the methyl synthesis, assumed by previous investigators, really does take place when tellurium is administered and that the garlic odor arising as a consequence is caused by methyl telluride.¹¹

In experiments on warm and cold-blooded animals he confirmed the observations of previous workers that the various body parts take on the same odor, and showed that it is strongest, or in other words the methyl synthesis is relatively greatest, in the testes and the lungs, and pronounced in the blood, liver and kidneys. He found that when the organs of an animal into which sodium tellurite had been injected intravenously, are put in a warm place (at 36° C.), the smell of methyl telluride is intensified about those having that odor to begin with and is gradually made distinct in others. Under the same conditions, blood loses it, however. Time and intensity vary, of course. These facts show that the cells of the glands are able to absorb tellurium and that they also have the power, at the body temperature, of forming methyl telluride from it. This substance is formed also by minced fresh organs from dogs and rabbits when they are treated with the same substance at the body temperature. Hofmeister proved that this synthesis, with production of the characteristic odor, takes place, also, in frogs, fishes, crabs, and even in earthworms, when small quantities of tellurite are given them.¹² The tellurium was deposited in the animals experimented on in large part in metallic form in many parts of the body, the reduction, judging from the discoloration, varying considerably.

In the body of a dog weighing 850 gms., into which 0.04 gm. of sodium tellurite had been injected intravenously, and which after bleeding to death had been kept at normal temperature for four hours, practically all parts were pigmented by tellurium except cartilage, bone and the white matter of the nervous system. When dosage was not too great, however, it was found that in the lungs and testes the tellurium, instead of having been deposited was transformed wholly into methyl telluride, which accounts for the fact that these organs are rarely colored by the bluish-black metallic deposits usually found in practically all of the glands. The long-continued elimination of methyl telluride in the breath, Hofmeister shows, is due to gradual syn-

⁸ It is interesting to note in this connection, that tellurium is transformed into some of the same products in reality as in Rabuteau's experiments, and also, as in the case of arsenic and antimony. Rabuteau, in some of the preceding experiments, found that the tellurium compounds, when administered, which appears to be the case, are precipitated by Mendel's solution.

⁹ Sodium tellurite, 0.01 gm., was injected subcutaneously into dogs and cats. As soon as the garlic odor became perceptible in the expired air, the latter was passed through a solution of sodium hydroxide, and the gas, for 20 to 48 hours. The solution decomposes the methyl telluride, liberates the alkyl groups and forms telluric acid, which is precipitated by sodium hydroxide, and treated with sodium sulphate. Telluric acid, after evaporation of the sodium, and treatment with nitric and hydrochloric acids, was precipitated in metallic flakes with sodium sulphide.

¹⁰ On the other hand, traces of tellurium salts in these animals, Hofmeister says, nothing like that in amount as in the case of sodium tellurite, and the soft parts of crabs is followed by paralysis and death.

⁸ We are left to infer the manner of introduction of tellurium in these experiments. It seems to have been both by way of the mouth and under the skin.

⁹ Also in having antidote action. See footnote farther on, where additional results of Czapek and Weil's work are given.

thetic transformation of the tellurium which had been deposited in the tissues in metallic form soon after its introduction. He suggests that the reduced tellurium is slowly transformed into the soluble sodium tellurate by the action of the alkaline tissue fluids before it reaches the lungs, and that it is there changed to the methyl compound. In this way he explains the persistence of the odor in the breath.

Hofmeister was unable to determine the specific source of the methyl for this synthesis, but, as the liberation of methyl groups, and also their incorporation in other substances like cholin and creatin, seem to be intermediate processes in general metabolism, he concluded, from his experiments, that the tellurium unites with methyl groups set free in some manner in the cells. He showed that this conversion of tellurium to methyl telluride, and the process of reduction of tellurium compounds, may take place quite independently of each other, for when fresh normal glands after maceration are warmed a few minutes, at 50 to 55° C., and then treated with sodium tellurite, their power to reduce is undiminished, although no methyl telluride is formed by them. The synthetic process is entirely prevented, also, after treatment of the tissues with solutions of various chemicals—even physiological salt solution.

Beyer, following the general suggestions of Ludwig, demonstrated, in some transfusion experiments on perfectly fresh kidneys with oxygen free and arterial blood containing sodium tellurate, that the methyl synthesis does not take place in the absence of oxygen, although reduction to the metallic state occurs in the cells quite independently of the character of the transfused blood. He sought also, by histological methods, to determine just where in the tissues the reduction of tellurium from its salts occurs. He injected small quantities of sodium tellurate, dissolved in physiological salt solution, into the jugular veins of dogs and rabbits, and found that granular metallic tellurium was deposited only in form elements; in nerve and glandular cells, leukocytes and striated muscle especially. Endothelium, unstriated muscle, nerve and connective tissue fibers, on the other hand, were found to have no affinity for tellurium. The deposit of metallic element in the cells did not appear to cause their degeneration. Destruction occurred only occasionally. The cells, for the most part, seemed to have the power of gradually removing the foreign material without loss of normal function, and even when quite full of the deposit behaved toward all the various staining reagents exactly as normal cells do. Even three weeks after injection of tellurate, while the breath still smelled strongly of methyl telluride, Beyer found metallic tellurium in the glandular cells. Its transformation must, therefore, have been gradual, as Hofmeister has shown was the case in other connections.

Increasing amounts of sodium tellurate injected into the blood of rabbits induced clonic convulsions, respiratory paralysis and death. The blood became laky. Lakiness was not produced by tellurate in rabbit's blood outside the body, which fact suggests that a tellurium transformation product caused it in Beyer's experiments. Intravenous injections, in dogs, of quantities of sodium tellurate ranging from 0.025 to 0.04 gm. per kilo of body-weight were quickly followed by death in some cases; at other times, by vomiting and loss of appetite, with recovery in several days. These quantities also brought about general paralysis; sometimes only of the

hind legs and masseters, but usually also of the intercostals, making respiration very labored. Fatty degeneration of the hepatic cells and destructive changes in the uriniferous tubules also resulted. The lymphatic vessels of the liver were found to be much enlarged and other structural changes were observed. In one case lymph from the thoracic duct had a grayish color, due to suspended tellurium.

The urine under these same conditions was turbid, greenish brown to a dark green in color, and gave off the odor of methyl telluride. It contained metallic tellurium, crystals of urocanic acid and triple phosphate; also, blood-corpuscles, albumin and bile pigment. The latter appeared in the blood-serum also. From the urine of a dog, collected during the first 24 hours after intravenous injection of 0.75 gm. of sodium tellurate (0.27 gm. Te), Beyer separated 0.062 gm. of metallic tellurium. From the urine of the second day, 0.081 gm. There was only a trace in that of the third. None in the fourth. More than one-half of the tellurium administered was, therefore, eliminated through the kidneys.

Until recently, a brief and imperfect experiment by Beyer, on the excretion of urea after intravenous injection of sodium tellurate, had been the only one to suggest the metabolic influence of tellurium. Beyer found that the normal amount of urea eliminated in the urine of a healthy dog, during three preliminary days, was 9.45, 10.41 and 7.62% respectively, an average of 9.16%. After injection of 0.75 gm. of sodium tellurate into the jugular vein, the urea in the urine on five successive days was 1.79, 6.06, 8.50, 7.98, 9.00%, an average of 6.67%. This marked falling-off in the amount of urea was due mainly to the refusal of the dog to eat on the first and second days of the tellurium period, and as Beyer does not give any analytic data regarding the food, it is impossible to attach any special importance to his results in this connection.

The author, very ably assisted by Mr. L. D. Mead, recently completed a series of experiments on dogs in which an attempt was made to ascertain, among other things, the effects of continued dosage of tellurium compounds. It was found that nontoxic doses of tellurium (in quantities several times as great as therapeutic doses and in the forms of oxide, tellurite, tartrate and tellurate) did not materially affect metabolism in dogs brought to a state of nitrogenous equilibrium, even when dosage was continued for a week. These substances appeared to stimulate proteid catabolism only slightly. They increased somewhat the weight of dry matter in the feces and diminished, in small degree, the absorption of fat. The urine was unaffected in volume, specific gravity, and reaction, but became dark brown in color during the dosage periods.

Excessive doses retarded gastric digestion; induced violent vomiting, loss of appetite and somnolence. They caused, besides, inflammation and disintegration of the mucous membrane of the gastrointestinal tract and, also, intestinal hemorrhage. Introduced under the skin, tellurium (tartrate) caused restlessness, tremor, weakening of the reflexes, somnolence, diarrhea, paralysis, unconsciousness, stoppage of respiration and death, in convulsions from asphyxia. At the point of injection much of the tellurium was deposited in metallic form, but it was also distributed in large quantity to most of the organs and tissues.

It was found, also, that tellurium compounds, even in small proportion, markedly arrested the secretion of

acid in the stomach—the direct cause, probably, of the indigestion brought about, not only in dogs but, as will be pointed out later, by tellurium compounds in man, also. Intestinal putrefaction was not influenced in any degree. The action of trypsin and pepsin outside the body was not very perceptibly diminished by quantities of tellurium compounds under 0.6%. Zymolysis was almost unaffected in the presence of as much as 1.25% of some of the salts. Ptyalin was more easily affected, even by the faintly alkaline tellurate. Trypsin appeared to be least sensitive to destructive influence, acting rapidly in the presence of even 2.5% of tellurite.

Tellurium was eliminated in metallic form in the feces; as methyl telluride in the breath, urine, feces, and epidermal secretions; in a soluble form, in small quantity, in the urine and in the bile. The urine was colored brown to yellowish green after heavy dosage with tellurium compounds, but return to normal coloration was rapid after administration had been discontinued. Albumin and bile pigment, besides tellurium, were the abnormal constituents of the urine found after subcutaneous injections. Toxic quantities given by the mouth caused the appearance of coagulable proteid, but no bile pigment, in the urine.

C. Influence on Man. (a) *General.*—Berzelius,¹¹ who led the way for so long in chemical studies of tellurium, found, from personal experience, that hydrogen telluride is irritant in its action and more poisonous in effect than the corresponding compound of sulphur. Berzelius and Köreuter¹⁴ have reported that the oxides of tellurium, as well as a number of salts of telluric and tellurous acids, have a very unpleasant metallic taste resembling that of compounds of antimony and that some have a nauseating action and are strongly emetic.

Wöhler, at the time of his discovery of ethyl telluride,¹⁵ referred to the disagreeable odor of that substance, and stated that it is very poisonous. At that time, and subsequently, while engaged in his chemical researches on ethyl telluride, Wöhler observed that his sweat and breath took on an odor closely resembling that of the substance he was working with.¹⁶ One night, while perspiring very freely, the garlic odor in his sweat became so great that he himself could hardly bear it. It persisted in his breath for weeks. These facts led Wöhler to suggest the physiological researches made in his laboratory by his pupil, Hansen.

The latter was the first to experiment systematically on man with tellurium compounds. For 7 successive days he himself took neutral potassium tellurite an hour before dinner. On the first 4 days 0.04 gm., on the 2 following days 0.05 gm., and on the last day 0.08 gm.—a total of 0.34 gm. During the first two days very unusual sleepiness was the main symptom. Later it disappeared. At the beginning there was increased appetite, but later the appetite was reduced. After dosage on the last day there was a sense of oppression in the cardiac region, also nausea and abundant salivation. The tongue was heavily coated with a white deposit, and there was complete loss of appetite. The gastric symptoms did not disappear completely until after a lapse of 2 weeks, and the alliaceous odor of the breath continued 7 weeks.

The characteristic odor of the breath was noticed within a few minutes after the first dose had been taken,

and soon became so strong and so obnoxious to others that his own seclusion was necessary for their comfort. At that time the odor was attributed to a volatile compound of tellurium identical with or similar to ethyltelluride. Hansen was unable to separate any tellurium from the urine; not even from that passed during the first 24 hours after the last dosage. Experiments on his friend, von Röder, who took 0.04 gm. of acid potassium tellurite before dinner one day, and nearly 0.05 gm. at the same time the next, presented essentially the same results. Hansen refers to Wöhler's previous experience and says that during these later experiments in the latter's laboratory Wöhler observed the same phenomena, with regard to himself, a second time.

Heeren,¹⁷ also working under Wöhler's direction, on the chemical nature of various compounds of ethyl and methyl tellurides, noted that the garlic odor of the breath was especially strong in his own experience when methyl telluride or any of its derivatives was under examination. He states that even when these products are merely touched with the fingers their characteristic odor is carried to all parts of the body and in a few days the breath also acquires it, the odor quickly becoming so obnoxious that, as he puts it, "one must avoid all social life for months, so as not to annoy others."

Sir J. Simpson records a case¹⁸ in which a student inadvertently swallowed a dose of tellurium, which was followed by the evolution of such a persistent odor that for the remainder of the session he had to sit apart from his fellow students.

Prof. Victor Lenher, who for several years has been engaged in chemical studies of tellurium, greatly favored the author with a statement of his toxicological experiences for use in this connection. After inhalations of the volatile tellurous oxide, which he formed repeatedly in preparing metallic tellurium by the fusion method, Prof. Lenher's breath and the excretions from his skin took on the usual garlic odor. Metallic taste was noted and nausea also frequently experienced. The odor of the breath in one case persisted for about a year. General depression followed continuous inhalation of the oxide, and in one instance a prolonged period of somnolence resulted, an experience similar to Hansen's after ingestion of tellurite. Severe constipation was also a marked symptom following tellurium inhalation. At no time could Prof. Lenher detect any tellurium in his urine, not even during the periods of his worst experiences.

The author has found in his own experience that when the methyl telluride which had been exhaled by the dogs he experimented with was taken into his own lungs, an alliaceous odor of the breath and excretions from the skin soon became noticeable and continued persistently. Also, that such inhalation was accompanied frequently by short periods of drowsiness and nausea.

The presence of "telluric breath" and the alliaceous quality of the breath that it produced. As early as 1875 tellurium had been suspected in commercial preparations of bismuth.¹⁹ The evidence on this point at that time was not of an analytical character, but was based upon the observation that people to whom certain bismuth preparations had been administered suffered from fetid breath. The presence of tellurium in bismuth

preparations has since been repeatedly shown,²⁰ and their medicinal use implies frequent incidental action of this tellurium impurity.

Reisert, in 1884, after an investigation of the cause of the so-called bismuth breath, ascertained that it was due, as had been supposed by some, to the minute tellurium impurities often found in the commercial bismuth compounds used in medicine, and not to arsenic or bismuth itself, as had been assumed by others.²¹ He not only demonstrated, in some experiments on himself and friends, that the "bismuth breath" did not follow dosage with chemically pure bismuth sesquioxide, or arsenious oxide, but also determined the minimal amount of tellurium which would produce the alliaceous odor in the breath. He found that as little as 0.000,000,5 gm. of tellurous oxide, given in solution to men, was followed by the smell of garlic in 75 minutes, and that it continued for about 30 hours; 0.000,000,3 gm., given to three different individuals, failed to produce a detectable quantity of the odor. In one experiment, three doses of 0.005 gm. each were taken on the same day at intervals of 3 hours. "In 15 minutes after the first dose the breath had a strong garlic-like odor, and in an hour a metallic taste was observed. An hour after the second dose the urine and sweat had the garlic-like odor, which was also observed in the feces, 4 days later. The metallic taste was observed for 72 hours; and the garlic-like odor in the urine for 382 hours, in the sweat for 452 hours, in the feces for 79 days, and in the breath it was still present, though very faintly, after 237 days."

Reisert passed his breath through a tall column of distilled water for several hours, in the hope of catching the odoriferous compound which seemed to be eliminated from the lungs in appreciable quantity, but analysis of this water afterwards gave negative results. He assumed, therefore, that the quantity of substance responsible for the odor was too small to be detected by known chemical means and suggested that the "physiological test" is much more delicate than any purely chemical one for this purpose.²² Reisert concluded his paper with the remark that idiosyncrasy did not seem to have any influence in his experiments, since the breath of every one to whom the tellurous oxide had been administered, in quantities not less than 0.000,000,5 gm., was affected with the alliaceous odor.

(c) *Antihydrotic Action and Therapeutic Use.*—Neusser was the first to show that tellurium compounds are of therapeutic value. In about fifty clinical experiments, on as many consumptives, he observed that the night-sweats were very perceptibly reduced after administrations of potassium tellurate in daily doses of 0.02 to 0.06 gm.²³ In a majority of cases 0.02 gm. was sufficient,

although cumulative dosage was necessary at times to effect continued results. He noted, also, that these amounts did not cause any particularly toxic symptoms, although mild dyspepsia (eructations, coated tongue, loss of appetite) was produced now and then by the use of the largest dose. In some cases there appeared to be stimulation of appetite at first and, in quite a number of instances, Neusser received the impression that slight narcotic action had been manifested. The breath of each individual experimented on always quickly assumed the characteristic alliaceous odor even with the smallest quantities of the tellurate. This was the only undesirable feature that occurred regularly. Neusser stated that the odor was not noticed by the patients themselves except in a few cases. Sulphurous and camphoraceous odors in eructations were sometimes complained of. His experiments were conducted on patients in advanced stages of phthisis, but with none of these was any favorable influence of the tellurium observed on the disease itself.

Pohorecki, following Neusser's lead, confirmed, in a large number of clinical experiments, the latter's results in practically all particulars. He reported that increased appetite and better general nutrition resulted from dosage with 0.01—0.02 gm. of potassium tellurate in the earlier stages of phthisis. Anidrotic action was manifested in fifteen minutes to an hour, and continued five to seven hours. The garlic odor of the breath could be detected fifteen minutes after administration and continued four to eight weeks. Even in people who were perfectly well it was observed that potassium tellurate greatly hindered the secretion of sweat.

Combemale and Dubiquet found that sodium tellurate in daily doses of 0.02 to 0.05 gm. had a pronounced antidiaphoretic action and was more effective in this respect than even camphoric acid. Anidrosis was obtained not only with patients suffering from phthisis, but also in other cases in which sweating is often profuse (rheumatism, dyspepsia, etc.). Administration of sodium tellurate was followed by diminished perspiration in 18 of 20 cases. In 6 of the 18 it was arrested completely. 0.02 gm. was found to be the minimal dose which would induce anidrosis; 0.05 gm. the most effective quantity. Repeated dosage with this amount for a few days brought about the result, if it was not manifested immediately after the first administration. These observers, unlike Neusser in his experiences with the potassium salt, did not find that any gastrointestinal disturbances were set up and report the alliaceous odor of the breath in but a few instances as the only objectionable feature following its administration in the doses indicated and for reasonable lengths of time.²⁴ Combemale and Dubiquet consider sodium tellurate the very best anidrotic agent and prefer it as a result of their experiments to camphoric acid, white agaric, atropin, phosphate of lime, etc. Combemale favors the view that excessive sweating, in such disorders as phthisis, is due to the action of ptomaines elaborated by the specific germs of the disease and he supposes that sodium tellurate exerts an antihydrotic influence by rendering these soluble septic products innocuous.

²⁰ Lately again *Deutsches Archiv für Klinische Medizin*, 1894, xxxviii, 256, referring to observations of Janzon in *Pharm. Zeitsch.*

²¹ The author is greatly indebted to Prof. John Marshall for calling his attention to Reisert's work. It seems that subsequent foreign investigators of the behavior of tellurium in the animal body were influenced by Reisert's results. It is probable, however, that Kuukel refers to these results when he says, "The odor (of methyl telluride) has been detected in the feces of man over two months, and in the breath more than a half year, after the last dose of tellurium." *Handbuch der Toxikologie*, 1899, 365.

²² Reference has already been made to Hofmeister's method for separating tellurium eliminated in the form of methyl telluride in the expired air. This was not applied, of course, until after Reisert's work had been reported. Reisert knew, however, that Wöhler and his pupils attributed this odor to methyl telluride, but he failed to use adequate means for the retention and chemical detection of such a volatile compound.

²³ In order to test the anidrotic action of tellurium, Czapek and Weil, whose work has already been reviewed, made careful experiments in this connection on kittens with results that entirely confirmed Neusser's original observation. Moderate nontoxic doses (presumably of tellurates) were given and before any of the usual sickening influences had manifested themselves the moisture on the soles of the hind paws became less and less, until they were quite dry, when even the strongest electrical stimulation of the peripheral end of the divided sciatic nerve was insufficient to call forth secretion; after the tellurium had

reached the blood the effect of the anidrosis, however, was a direct peripheral action. These investigators were unable to determine any pathological changes in the structure of the sweat glands and concluded that the interference with secretion was a direct peripheral action of the tellurium and not one upon the central nervous system.

²⁴ The reported absence of the garlic odor in the breath in a large majority of these cases is in direct disagreement with the results of Reisert's quantitative experiments and the observations of all previous and subsequent investigators, except Rabuteau, each of whom has found that it invariably follows the introduction of very small quantities of tellurium into the system of man and lower animals.

He presents nothing, however, in direct evidence to substantiate this deduction. His theory would not explain the reduced sweating in perfectly well people, which Pohorecki observed after administration of potassium tellurate.

Mr. Mead and the author have shown, as has already been pointed out, that tellurates, in quantities not excessive and yet much greater than the therapeutic doses in man, exerted no particularly deleterious effects on the nutritional processes in dogs, even when dosage was continued for a week, although proteid catabolism seemed to be slightly stimulated after a time, and secretion of acid in the stomach retarded. The alliaceous odor imparted to the breath appears, therefore, to be the chief objectionable feature constantly following the use of therapeutic amounts of tellurates.

SOME MODERN GYNECOLOGICAL RESOURCES.

By AUGUSTIN H. GOELET, M.D.,

of New York.

Professor of Gynecology, New York School of Clinical Medicine; Consulting Professor of Gynecological Electro-Therapeutics, International Correspondence Schools, Scranton, Pa.; etc.

THE accompanying illustrations were inadvertently omitted when my paper on "The Resources of Modern Minor Gynecology" appeared in this JOURNAL, January 5.

Fig. 1 represents a four-branch dilator for extending the degree of dilation of the cervix uteri beyond what is possible with the two-branch instrument. It is the only satisfactory dilator expanding in more than two directions that I have seen or used, and is a very useful instrument where extensive dilatation of the cervix is required. It is a very powerful instrument, however, and used carelessly will rupture the cervix. A stop which may be adjusted at any point is arranged so as to limit the dilatation to any degree required, thus limiting the amount of force applied.

Figs. 2 and 3 represent a rubber cover for sponge or laminaria tents whereby this very useful means of dilating the cervical canal may be employed in a perfectly aseptic manner. It was because of the impossibility of effecting aseptic dilatation with these tents that they were abandoned. The tents could of course

be rendered aseptic, but their expansion when placed in the canal depended upon the absorption of secretion from the surface and glands beneath. Hence this secretion which so often harbors bacteria is taken up by the tent and conveyed to the endometrium of the cavity above where the bacteria find a fertile field for development.

By using the tent-covers the tent does not come in

FIG. 1.—Author's four-branched dilator.

contact with the surface, but expands within the cover by absorption of moisture from gauze placed in the vagina.

Fig. 2 represents the cover.

Fig. 3 represents the cover with the tent within it and a piece of gauze covering the tent, one end of

FIG. 2.—Author's tent cover.

which projects from the opening of the cover so as to come in contact with the moist gauze placed in the vagina after the tent has been inserted. They are sterilized either by boiling or by emersion for 20 minutes in synol soap, full strength.

The method of using the tent is as follows, viz., the

FIG. 3.—Author's tent cover over tent ready for use. Shows strip of gauze surrounding tent with one end projecting.

tent is drawn over a pair of sterile dressing forceps closed and rolled in the same manner as the finger cot, from the opening to the closed end, to facilitate getting it over the tent; the tent is then covered with a narrow strip of absorbent gauze placed lengthways with one end projecting considerably beyond the lower end of the cover. The gauze is now made thoroughly wet by

dipping it, tent and all, into water. Then the cover is unrolled over it, leaving the long end of the gauze strip projecting beyond the opening of the cover.

The tent with cover over it is grasped with a pair of uterine dressing forceps and dipped into synol antiseptic liquid soap to lubricate it, then fixing the cervix (exposed through a vaginal speculum), by means of a pair of angular tenaculum forceps the tent is inserted

FIG. 4.—Author's uterine endoscope, showing the different parts detached.

into the cervix up to its full length, and the vagina is filled loosely with absorbent gauze to retain the tent in position. The gauze in the vagina is then thoroughly moistened with sterile water before the speculum is withdrawn. The vagina and vulva are to be previously sterilized as for curettage.

For the benefit of the younger members of the profession who are unfamiliar with the use of sponge tents, I will say that about 24 hours are required for the complete expansion of these tents and during that time the patient should be kept in bed in the recumbent position.

Figs. 4 and 5 represent the uterine endoscope for inspecting the interior of the uterus which I introduced about 2 years ago.

Fig. 4 represents the instrument with the several parts detached and shows the small electric lamp near the extremity of the endoscope tube where the light is placed for direct illumination of the cavity.

Fig. 5 represents the endoscope tube in position in

FIG. 5.—The uterine endoscope in position.

the uterus with megaloscope in position for magnifying the field. Illumination of the lamp is secured by 4 dry Leclanche cells arranged in series and placed in a box for transportation, in the top of which may be stored the different size endoscope tubes (3 in number) with their obturators, the connecting cords, etc.

The diagnosis of disease involving the endometrium is obviously imperfect without the aid of inspection

afforded by the uterine endoscope. With this instrument it is possible to determine whether it is necessary or not to employ the curet, and after curettage to decide if the work has been properly and thoroughly done. Without such aid these points are often only a matter of conjecture.

Fig. 6 represents a clinical double current uterine irrigator which possesses many advantages. The stream is projected from the end of the tube in a fan-shaped jet and the opening is so arranged that if the extreme point is pressed against the fundus the stream can escape from the sides, thus the flow does not become obstructed. The outer tube is conical, enlarging from the end to the point of exit so as to obviate obstruction of the return flow from the cavity.

The end of the tube is small enough to be introduced through the canal of the cervix and internal os in most cases without previous dilatation of the canal.

Hence the instrument is useful for clinical irrigation of the uterus both previous to and after dilatation and curettage. (There is a larger size of the instrument for use when the cervix is dilated, known as the operating irrigator.)

When the clinical irrigator encounters obstruction in

FIG. 6.—Author's clinical double current uterine irrigator.

the canal and does not enter readily it may be converted temporarily into an electrode by slipping over it a piece of rubber tubing for insulation, extending from the projection for the outflow on the outer tube to within 2½ or 3 inches of the end. There is an attachment on the handle near where the tube from the reservoir is attached for connecting the cord from the battery. If this irrigator thus arranged is connected with the negative pole of the galvanic battery and a dispersing electrode connected with the positive is placed on the abdomen or over the sacrum and 10 M. of current is turned on the action of the current will so soften the structure of the cervix within a minute that the irrigator will slip through or by the obstruction. By permitting the current to remain on while the irrigation of the cavity is going on, thorough relaxation of the canal will be secured, sufficient for subsequent drainage.

This irrigator is positively indispensable in treating endometritis, to preserve cleanliness of the cavity and for making applications thereto.

Congress of Gynecology.—The Congress de Gynecologie of France will meet this year at Nantes, September 23 to 30. Foreign gynecologists are invited to attend.

DEJERINE-ERB TYPE OF UPPER-ARM PALSY FOLLOWING MULTIPLE NEURITIS.*

By D. J. McCARTHY, M.D.,

of Philadelphia.

Instructor in Nervous Diseases, Philadelphia Polyclinic; Associate in Medicine William Pepper Clinical Laboratory, University of Pennsylvania.

MULTIPLE neuritis, caused by alcohol, is not an uncommon affection. Bilateral wrist-drop in workers in lead, caused by the toxic action of the lead on the peripheral nerves, is of rather frequent occurrence. The probable action of both of these poisons in the production of the symptoms in the case here reported, makes it one of considerable interest.

J. G., age 28, compositor by occupation, was admitted to the clinic October 15, 1900, suffering with paralysis of both arms and weakness of both legs. His family history and previous history revealed nothing of importance. For several months he had been drinking heavily, and 3 weeks previous to the time of his admission had an attack of abdominal pain with marked constipation. He thinks this was an attack of lead colic. Following this attack he became very nervous and during the following week rapidly lost power in both arms. At the end of the week the paralysis of the arms was so complete that he was unable to lift them to the horizontal position, or to dress or feed himself. During the following week he rapidly lost power in the legs and was compelled to go to bed. There was at that time dull, aching pains in the arms and shoulders worse at night. He remained in bed 2 weeks. The legs rapidly regained their tone and he is now able to walk with comfort. There has been no numbness, no parasthesia, and no bladder or rectal trouble.

Examination reveals almost complete loss of power, with marked wasting in all the shoulder muscles of both sides. The supra and infraspinatus fossae are very prominent and show marked wasting. The forearm and hand is not wasted, but there is marked bilateral wrist drop. The grip is weaker than normal, but when the wrist is supported in extension, power is fairly well preserved in the median distribution. Reflexes are lost; and there is tenderness along the course of the nerve-trunks. In the lower extremities there is a very marked diminution of power in all the muscles, with loss of reflexes, tenderness over the nerve-trunks and muscles, but with practically no wasting atrophy of any muscles. The electrical examination shows reactions of degenerations in all the muscles about the shoulder girdle, with partial reactions and delayed contraction in the forearms and hands. The eye examination revealed diplopia due to palsy of the right internal rectus. A distinctly marked blue line is present on the gums.

This case should be considered as representing the double etiology of alcohol and lead in the production of multiple neuritis for the following reasons: In the first place, the presence of the blue line on the gums and the history of an attack of lead colic, is sufficient evidence of the presence of lead in the system in sufficient quantity to produce changes in the nervous system. In the second place, the predominance of extensor involvement as exhibited in the bilateral wrist-drop, with a fair preservation of the grip, and all forms of sensation, follows the usual clinical picture of lead palsy of the upper extremities. The evidence in favor of the presence of the alcohol as a factor in the production of the neuritis is found in the predominance of the changes in the peripheral, intramuscular nerve filaments in the lower extremities, over the trunk changes. The muscles were very sensitive to pressure even after the acute symptoms had subsided, while the nerve-trunks were only moderately sensitive, and only deep pressure elicited pain.

Sensitive and painful muscles are as rare in cases of

lead neuritis as they are common in alcoholic neuritis. Wrist drop, on the other hand, is so frequent in lead neuritis that it is looked on as the typical clinical picture of that disease. The intense atrophy coming on so rapidly after the development of the neuritis, less than four weeks, is rare in either form of neuritis, and is practically never met with in lead. We must look on it as an evidence of an intense change taking place either in the peripheral nerves, or the anterior horn cells of the spinal cord, or both, induced by the double intoxication.

The patient continued to improve under rest, galvanism and small doses of strychnin, and at the end of three months presented the clinical picture of the so-called Duchenne-Erb type of combined shoulder paralysis. To this was added extensor palsy of both forearms producing bilateral wrist-drop. Erb considers this type of palsy to be due to a lesion affecting the fifth and sixth cervical roots. It is usually the result of direct or indirect trauma, although Erb saw it result from the intoxication of tainted meat. Heyse reports a case in a tuberculous patient and Kraft-Ebing and Oppenheim have seen it the result of intoxication as in our case. The involvement of the deltoid, biceps, supraspinatus, infraspinatus, triceps, supinator longus, and the extensor carpi radialis and ulnaris corresponds closely to the type described by Erb. While the other muscles of the upper extremities were at first affected, they recovered their tone in a short time, and were not involved in the intense atrophy present about the shoulder.

Lead intoxication from type, at one time so common, is at present of infrequent, even rare, occurrence. This is due to the fact that the type of today contains but little lead; zinc and other metals are employed to harden the type, and the small percentage of lead is not usually deleterious in its effects.

The combined effect of lead and alcohol on the nervous system can rarely be differentiated with such clearness as in the present case. The lead had probably little to do with the manifestations in the lower extremities; the paralysis and sensory changes following here the alcoholic type. The intense wasting about the shoulder girdle is probably the result of the combined effect of both the alcohol and lead, as the palsy of the forearm followed clearly the lead type, to which was added in the upper arm the tenderness over the nerves and the reactions of degeneration.

I am indebted to Dr. Wm. G. Spiller, from whose clinic at the Philadelphia Polyclinic this case is published.

A NEW TREATMENT FOR TUBERCULOUS GLANDS OF THE NECK WITH MINIMAL SCARRING, INVOLVING A METHOD OF STERILIZING A TUBERCULOUS REGION THROUGH THE LYMPH CHANNELS.

By G. BETTON MASON, M.D.

of Philadelphia.

THE recognition of the tuberculous nature of what were formerly known as scrofulous enlargements of the lymphatic glands of the neck has opened a new vista in the treatment of this affection. The disease should no longer be looked upon as a constitutional affection, controllable only by general treatment, but should be understood as a local implantation of the bacillus

* Read at the Philadelphia Neurological Society, November, 1900.

* Read before the Philadelphia County Medical Society, February 13, 1901.

tuberculosis in an individual whose inherited type of cell constitution is not proof against its implantation. In these particular cases, the tuberculous germs doubtless gain entrance into the lymphatic vessels of the neck through an infection atrium in the tonsils, and are arrested in the first gland reached by them, there to multiply until the gland is eroded, permitting the next one in the chain to be infected, and so on, throughout the chain.

It is evident that mere constitutional treatment of this condition, while both appropriate and valuable in strengthening the phagocytic powers of the body cells and fluids, is but a sorry method of reaching an entrenched colony already in vigorous growth. Moreover, these colonies of germ growth are just beneath the skin, and therefore are more accessible than tubercular deposits in the inner organs of the body.

The removal of the infected glands by the ordinary cutting operation has the disadvantage of leaving unsightly scars, which are seriously objected to by patients for cosmetic reasons. When the capsules of the glands are eroded through, their removal is more difficult, and gives rise to a more extensive scar.

Efforts to cause absorption of these enlargements by the percutaneous application of electricity, or by percutaneous cataphoresis, have been equally unsuccessful in my hands, and the reason is evident when we consider that the vital resistance of these germs, though not great, is quite sufficient to resist any agents or influences that are transmissible through an intact skin. When applied to more than a year ago by a physician to treat such a case, therefore, I immediately determined to try a modification of my cataphoric method for the destruction of cancer, and as the application of this modified method was an unqualified success in this case and in that of another case in which it has since been employed, its presentation to the medical profession is now made with much confidence in its value.

The object of the method is the destruction of the bacilli by the cataphoric diffusion among them of nascent oxychlorid of mercury, developed in their midst by the electrolysis of metallic mercury held in contact with a small gold electrode. A small opening is made through the skin and into the gland by a narrow bistoury, under a chlorid of ethyl spray, and into the opening is thrust a sliver of amalgamated zinc to act as an anode, not insulated, of a weak galvanic current—one to three milliamperes—which is turned on gradually and maintained for a few minutes to cauterize the tract and keep it patulous for the treatment proper. When the tract has received a sufficient impregnation with the mixed oxychlorids of zinc and mercury thus developed to keep it patulous for a few days, the zinc electrode is withdrawn and an insulated gold electrode about the caliber of a piece of No. 18 wire is inserted, its point having previously been amalgamated and made to hold as much mercury as possible. This instrument is left bare for $\frac{1}{4}$ inch from the point only, in order that all the current action shall be expended within the gland, the remainder of the instrument being insulated with fused hard rubber or fused shellac. From 2 to 10 milliamperes is now turned on and maintained for 10 minutes, or until all the mercury has been dissipated from the gold surface, after which a piece of absorbent cotton or lint is placed over the opening, topped by a piece of plaster, and the patient returns at intervals of two or three days for a repetition of the application. The endermic applica-

tion of cocain may be used to deaden the slight pain of these applications, a mere drop of a 10% solution placed in the opening being an excellent preliminary to the later applications.

The purpose of the sinus thus formed is the drainage of the products of the dead bacilli and deposited chemicals as well as for a direct application to the germ colony. Small doses and the gradual method of treatment are adopted to avoid unnecessary destruction of the gland tissue or the production of solid eschars that would not readily drain away, the repeated applications acting in a cumulative way on the protoplasm, finally destroying all pathogenic germs by the combined effects of the direct action of the germicide and the indirect action of the aroused trophic forces of the surrounding normal cells.

Observation of the two cases to be reported has caused me to believe that the germicidal action is not confined entirely to the gland to which the application is made, but that the chemicals deposited in this situation drain downwards to the next glands in the chain and favorably influence any infection in these glands.

The final result is the destruction of the tuberculous bacilli, without necessarily destroying all the gland tissue not destroyed by the disease, and when the opening is allowed to close the scar left is a mere point, and the general health of the patient will be found to be improved. The sinus requires no special precautions against septic infection while open, by reason of the powerfully antiseptic chemicals deposited within and about it.

CASE I.—Mr. B., a stenographer, was referred to me by Dr. E. E. Johnson, of Philadelphia, February 15, 1899. The family history was good. In July, 1898, a tuberculous gland was removed by means of a cutting operation by a physician of York, Pa. The wound failed to heal, and Dr. Johnson cauterized it the following month. When first seen by me there was a large scar on the left side of the neck, near which a tuberculous gland of large size was located. The patient's color was pale.

A small opening was made under chlorid of ethyl spray, the opening was made patulous by means of the zinc mercury sliver as an anode, and subdermic mercuric cataphoresis was applied by means of the insulated gold instrument about twice a week, the patient covering the spot between times with a bit of adhesive plaster and continuing at his usual occupation. In all, 11 applications were made in 7 weeks, when the gland itself seemed to be softened and hollow, surrounded by an area of treatment induration. The opening was now allowed to close, subsequent observation showing a progressive shrinkage of the induration.

This patient was not seen again until 4 months after the cessation of the treatment, when the induration had disappeared, leaving a minute round scar in the skin, and he seemed to be in decidedly more robust health. He states at present that he is in better health than for fifteen years.

CASE 2.—Miss G., also a stenographer, applied for treatment in May, 1899. Her parents are healthy, but there was consumption on both sides in the grandparents' generation, and a sister and brother now have pulmonary tuberculosis. Examination showed two enlarged glands on the right side of the neck, rather alongside of each other than in the same chain. Below these glands there were a number of smaller ones. The patient complained of some stiffness and pain in the neck when tired, and was anemic and menorrhagic.

The method detailed above was employed 19 times to August 22, 1899, when one gland was shrivelled, and it was evident that the glands below were smaller. Treatment was then stopped in this focus of the disease, and she was placed under a brief similar treatment for the other gland.

After but a few applications were made, the patient noticed that she no longer had the stiffness and dull ache in the neck. Her general health was immediately improved by the treatment, so much so, indeed, that she ceased attend-

ance before I thought the second gland, to which I was making applications, had received enough of the cataphoric salts. Her weight increased, the menstrual pain ceased, and she very shortly showed the evidences of blooming health which you will notice tonight.

On examining the neck tonight, a year and a half after the brief treatment described, you will notice a small, white scar less than an eighth of an inch in diameter at the site of the first gland punctured, and beneath it, what is apparently a healthy gland, but slightly larger than normal. The other scar is equally indistinct, and seems to overlie an equally healthy gland. But probably the most interesting fact of all is the shrinkage of the other glands of the neck below those treated, these being today but remnants of the knobby chain that extended down the neck into the supra-clavicular region. It is evident that the sterilizing mercurials that were cataphorically diffused into the uppermost gland also sterilized those below in the lymphatic channels while flowing through them. The importance of this observation in indicating one method of actually curing a form of tuberculosis is quite evident.

STRANGULATED AND GANGRENOUS HERNIA. KE- LOTOMY AND LAPAROTOMY IN STRANGULATION. EXTERNAL AND INTERNAL; ARTIFICIAL ANUS —ENTEROSTOMY, PRIMARY OR SECONDARY RESECTION—ENTERECTOMY, AND END-TO-END OR LATERAL JOINTING IN GANGRENOUS HERNIA.*

By THOMAS H. MANLEY, PH D., M.D.,
of New York.

(Continued from page 526.)

PART IV.

A BRIEF RESUMÉ ON THE EVOLUTION OF INTESTINAL SURGERY AS IT APPLIES TO STRANGULATED HERNIA.

The first cases recorded in surgical literature in which efforts were made to remove a section of diseased intestine were those of strangulated hernia. Littré, in 1699, closed a chasm in the intestine after gangrene, refreshing the edges and closing by circular suture. Von Bamdohr, surgeon to the Duke of Brunswick in 1727, resected successfully two feet of gangrenous intestine; operating by invaginating one divided end into the other. Twenty years later Durverger removed two inches of a gangrenous gut and joined the ends over a 4-inch section of the dried trachea of a calf; this coming away on the twentieth day, *per rectum*, and the patient recovering—1747. Peyronia again successfully resected four inches of the intestine in 1753. These pioneers were not without imitators and zealous disciples, but the mortality was so great that Lewis, writing late in the last century, formally condemned every description of intestinal surgery in strangulation, except the formation of an artificial anus. This eminent authority, however, bestows great praise on Littré, and pronounces his achievement "d'une merveille de l'art."

In the first half of the present century there are but two cases recorded of successful resection and jointing for mortified intestine; one by Levielle, 1812, and one by Diffenbach, 1836.

Animal Experimentation, Etc.—The foundation of rational and scientific surgery of the intestine rests on

modern animal experimentation; nay, a mastery of its art and technic are possible, chiefly by resort to this means.

In pre-anesthetic times it was, in a large measure, a failure. For example, as early as 1740 Moëbus and Farcy, after enumerating a large number of experiments on the intestine of the dog, conclude from this experience and results, that intestinal resection is utterly impracticable on the human being. Early in the century (nineteenth) there was a notable re-awakening in the French school on the subject of intestinal surgery. Jolly, Joubert and Lambert instituted a large number of experiments on the lower animals' intestine; several devices for jointing were devised. Lambert, a young hospital interne, described his suture before the French Academy in 1824. In 1825, Richerand tested the utility of the new modes of effecting enterorrhaphy in man, with disastrous results. Reyberd, in 1843, undertook to unite the divided ends of the colon after resection of a cancerous mass involving its ascending portion. His patient survived, but union failed and a large fecal fistula followed.

The results thus far were so unsatisfactory and the mortality so great that the best surgeons in Europe looked with disfavor on any description of surgery which entailed a section or resection of the intestine. In the brief space of five years after Reyberd's failure, the discovery of pulmonary anesthesia in America was announced, an event of incalculable magnitude to operative surgery; and yet we find that the deeply grounded, superstitious fear of opening or manipulating the peritoneum, stayed the hand of the surgeon. Not until the antiseptic treatment of wounds was generally adopted did intestinal surgery share in the impetus of modern advance, although this is of secondary importance in surgery, to anesthesia with ether or chloroform narcosis.

In 1873, Lücke, of Strasburg, again revived the operation of intestinal resection for gangrenous hernia, removing 6 centimeters of gut and losing his patient.

In Germany, notably after Thiersch's failure in 1879, the surgery of the intestine made surprising advances. To the Germans are we indebted for a large part of the knowledge we now possess on the art of intestinal surgery. Dr. Carl Beck, of New York, in 1879, made an extended series of experiments on induced gangrenous hernia, the deductions from which have since been utilized with signal advantage.

It is, as Bouilly has observed, remarkable to note that in France where intestinal surgery was first made the subject of a most extended experimental investigation, surgeons were skeptical and were very reluctant in sharing in the revival of this phase of operative surgery. Thus, in 1883, Dr. Bouilly was able to collect 38 cases of primary resection for gangrenous hernia reported from 1873 to this date; but one of which came from French sources. Serrè, writing on this topic, says that "we may date the real advance in intestinal surgery from 1873. I must repeat that we can only regret that these operations founded by the experimentations of French surgeons, the glory of the achievement is ours, executed by principles conceived by us and abandoned by the country that gave them birth, so that it is now quite exclusively from foreign sources that recent cases are reported." This author pronounces successful primary resection of the gangrenous bowel with effective jointing the greatest triumph of modern surgery.

* Read at the Pan-American Medical Congress, Havana, Cuba, February 4, 1901, before the Section on Gynecology.

America was destined to play a rôle of stupendous importance along this line of advance. In 1888, the illustrious Senn, of Milwaukee, at the International Medical Congress held in Washington, D. C., submitted the most extraordinary essay that ever was written on intestinal surgery. It was based entirely on exhaustive experimentation and yet the logical convictions deduced from so large and diversified a number of experiments, their general success, their scientific foundation, their precision and skill in execution, promptly assured surgeons of their applicability to the human being. The presentation of this great, unrivalled essay was hailed as the dawn of a new era in the surgery of the alimentary canal, and at an early date the fundamental principles it inculcated were successfully established on a large scale by the leading surgeons of the civilized world. In 1891, Dr. John B. Murphy, a brilliant young surgeon of Chicago, published a description of his anastomotic disc, the "Murphy button," a most extraordinary piece of ingenuity which it appears no description of modification can ever improve. It is generally conceded that no device ever invented has imparted the enormous impetus to the intestinal surgery that this has. For end-to-end jointing of the intestine it is simply unrivalled.

Gibson pronounces it the best and safest of all the various expedients at our command. A large number of other devices have been employed to assist in effecting union of the divided intestine. The last, and one of the most valuable of all measures yet suggested for jointing the divided intestine, was devised by Dr. M. E. Connell, of Milwaukee, now of Chicago. It displaces every description of apparatus or mechanical appliance, consisting of nothing more than a simple suture, specially employed.

In all of the above advances their success was only possible by animal experimentation. Lambert, on whose conception the initiatory was instituted, and whose principles yet hold with the vast majority, in his lifetime, never had an opportunity to test them on man, and Senn, Murphy, and Connell all published their essays before this method had yet been tested in resection of the intestine in the human being, their conclusions being entirely drawn from vivisection experiments.

PART V.

ARTIFICIAL ANUS, RESECTION OF THE INTESTINE, PRIMARY AND SECONDARY.

In cases of advanced gangrenous hernia, with or without perforation of the intestine, there are practically but two courses open to us for adoption; the one is to fix the dead parts in situ and drain the fecal contents through the inguinal or crural incision, when we have groin ruptures; the other is to resect the mortified parts and reconstruct the intestinal canal, and the time has now arrived when the "doubtful" cases should be dealt with in a similar manner.

Artificial Anus.—The attitude of our most noted surgical authorities widely varies on the choice of leaving an opening in the bowel involved by gangrene, or performing an immediate resection. Brief comments and statistics from various sources will be submitted on this aspect of the subject.

The establishment of an artificial anus is an imitation of nature's mode of relief, and cure also, when but a limited area of the gut is involved. In gangrenous cases the intestine above the stricture has usually con-

tracted adhesions, so that there is little to do in applying technic when an artificial anus is to be hurriedly made. Frequently, though not always, a patient with gangrenous hernia is in a state of great prostration, and there are signs of invasion of the general peritoneum. In 6 cases of artificial anus left after gangrenous hernia, in my own practice, in all the intestine was found ruptured. One had the gut opened for what was supposed to be a suppurating bubo. In 3, the general condition was not alarming at the time of kelotomy, but none survived more than 10 days. At the French Congress of Surgeons, in 1898, this subject was exhaustively discussed, and it was the opinion of the greater number that in gangrenous hernia the proper course to pursue was to *first* tap the bowel, and *later*, when reaction was well reestablished, perform a resection, a course which, from a theoretical standpoint at least, is unassailable. But the establishment of an artificial anus in strangulated hernia at best must be regarded as a confession of surgical impotency, and is a relic of antiquated methods, as Treves says: "The history of enterostomy is as old as strangulation itself." Dr. Carl Beck, of New York, was the first to decide the relative value of enterostomy and enterectomy from an experimental standpoint in induced strangulation in 55 vivisections. In 21 resections he had 14 cures; in 20 cases of artificial anus, 9 recoveries and 11 deaths. Though we do carry our patients over the breach with an artificial anus, a danger yet awaits him in a future jointing of the bowel, as no hope of cure may be looked for by the unaided powers of nature in artificial anus, when a section of the gut is done. Bouilly observes that "although we may find vestiges of fortunate tentatives which have been effected in the management of gangrenous hernia in the vast literature of ancient surgery, no mention is made of any means of cure of artificial anus. Richter alone, in 1700, thought it possible by anastomosis, but regarded it as altogether too dangerous an undertaking."

Mr. Spencer cites McCready as stating that at the present time, of 21 London surgeons, 17 favor artificial anus and but 4 the primary suture. Julliard's experience has been quite unique, as he records 20 cases of anastomosis for artificial anus with no deaths, after gangrenous hernia. Mr. Lockwood was able to collect 40 cases of gangrenous hernia treated after the method of Lawrence; viz., by a free incision through the mortified part in order to relieve the intestinal canal; or, if the intestine had already given way, to divide freely the integument and sac and leave the subsequent progress of the case entirely to nature, practically leaving an artificial anus. Thirty-six of these died—90%; 4 survived after a long and tedious convalescence, and had submitted to repeated operations to close their fistulae. This author regards incising the bowel as the most fatal; primary resection and suture the next in order of fatality, and the least, the enterotome. Kendall Franks, of Dublin, collected 202 cases of gangrenous hernia from various sources and in this number the mortality after artificial anus was 80.7%; after primary reaction, 47%. Ill collected notes on 29 cases of artificial anus in the United States; 25 died, 86% mortality. Mr. Wallace, of the Royal Manchester Infirmary, records 4 cases of artificial anus posthernial, all ending fatally. Chaput gives 80% as the primary mortality in above condition. Körte, 85.5%; Mikulicz, 76%.

Duplay fully describes the dangers, immediate and remote, connected with enterostomy of gangrenous hernia, and says: "Artificial anus may heal spon-

taneously, it may give temporary amelioration; but it most frequently tends toward death by inducing inanition, or, what is more frequent, death follows early from a persistence of symptoms and an extension of peritoneal invasion. But, more, in order to cure this repulsive state a fresh operation is involved, difficult of execution, grave in character and uncertain in results." The above well epitomizes this important subject; for look on it as we may, the construction of an artificial anus in gangrenous hernia can only be regarded as a *dernier ressort*, justified only when the patient is bordering on the moribund state or is in the hands of an incompetent surgeon. The economy of time in its construction has constituted one of its strongest claims; but M. Chaput pertinently observes that this has been exaggerated, that a resection and jointing may be effected in 30 minutes, a limit no greater than required in the formation of an enterostomy.

The repair of a fecal fistula—sometimes miscalled artificial anus—may occur of itself when the sphacelated patch is of an area which involves less than half the diameter of the intestine. Harrington records such a case, in a Littré's hernia; they are not very rare in this anatomical type of occlusion.

Localized or superficial, small plaques of gangrene we may sometimes encounter in kelotomies for strangulation. These are most frequently induced by violent taxis, the bowel has been severely crushed, the musculo-lacerated, the mucous lining detached, but the fibrous layer is intact. In these cases, the whole extruded coil has sustained serious damage, though there are only local expressions of it. These may often be grouped in the category of "doubtful" cases. We may treat them by (a) leaving the loop outside and waiting for time to decide; (b) we may resect the gangrenous patches and suture, or bury them under a row of Lembert sutures and reduce the affected loop; or (c) we may at once proceed to more radical measures and resect the entire extruded loop. We here must decide on that course which promises the best results, the least danger of peritoneal infection or loss of life by shock and exhaustion. When the vascular supply is not compromised, and the full vitality of the intestine is preserved, the exclusion of the small, ulcerated patches with a complete disinfection of the intestine will warrant immediate return of it to the abdominal cavity; caution, however, will require here that ample drainage is maintained until the danger of peritonitis is past. When, however, in conjunction with these localized contusions there is evidence of incipient gangrenous changes in the entire loop, free resection is called for.

PART VI.

PRIMARY RESECTION AND REESTABLISHMENT OF THE INTESTINAL CANAL IN GANGRENOUS HERNIA.

The successful resection of diseased intestine and the jointing of the divided ends certainly constitutes one of the very greatest triumphs of operative surgery.

Theoretically viewed, it appears like a procedure impossible of accomplishment. We know that a finger cleanly severed may sometimes be reimplanted; a part of the ear, the nose, or the integument may likewise be restored and take on vitality. Homologous reimplantation of various structures under aseptic precautions is frequently resorted to with satisfactory results. But to resect part of a tubular organ like the intestine, of

so complex a structure, and to unite it in such a manner as to ensure union and immediate recovery of function within a cavity so exquisitely sensitive to exposure or irritation as the peritoneal, seems to border on the miraculous; as Louis expressed it, "a marvel of surgical art." No wonder that it was only after the progress of ages and the futile efforts of numerous investigators, that in our time, with the aid of modern discoveries, intestinal jointing has come to be regarded as a legitimate and a life-saving operation. In gangrenous hernia, it is only within the last 10 years that enterectomy has generally been resorted to as a procedure at all warranted. It is only about 25 years since its great value here was first forcibly impressed on the profession.

The underlying principle of intestinal anastomosis or jointing is embodied in the discovery announced by Lembert, the seroserosus fusion of the intestinal walls; although the mode of introducing the suture in such a manner that only the serous and muscular layers be included, experiment and experience have proven of no essential consequence, as two of the latest and most effective modes of securing junction entirely ignore it—Murphy's and Connell's.

In gangrenous hernia calling for exclusion or the separation of the diseased from the healthy, immediate resection and jointing has the sanction of the majority of surgeons; want of accord is only noted in technic. It is well, however, to observe that in the near past many were hostile to primary resection. Deaver, of Philadelphia, *e. g.*, states it as his belief that "anastomotic operations are of value in but a few cases of strangulated hernia, . . . in hernia the condition of the patient does not warrant the procedure of anastomosis, and under the most favorable circumstances, the operation is anything but favorable." He had tried it more as an experiment, and lost all his patients. Resection and an anastomosis should not be "experimental" affairs any more than the performance of an appendectomy, but should be governed by well-established surgical principles; performed on patients *in extremis* it is a barbarity. Jaboulay pronounces "resection of the intestine as a difficult and grave procedure." Mr. F. Treves says that "in cases in which gangrene exists experience is against any attempt to unite the divided ends of the bowel immediately after the necrosed portion is excised. Such measures have been carried out with success in a few recorded cases, but it is a very hazardous procedure and neither the state of the patient nor the intestine will usually sanction the somewhat elaborate and possibly protracted operation." Mr. Treves is certainly in error when he speaks of "a few recorded cases" succeeding, as these are now comparatively numerous, in fact of such frequent occurrence, that many of them are not reported. With the proper preparation, the procedure is not at all perilous nor does it involve fresh risks. The only serious drawback is the frequent exhausted state of the patient, to such a degree as to justify no description of radical surgery.

Statistics from Philadelphia.—Within the past ten years there have appeared extensive statistical tables on the subject of the relative value of resection of the intestine for various pathological conditions. The first in this country, as it applied to gangrenous hernia by Dr. A. J. McCosh, 1889, the latest in the recent valuable contribution of Dr. Gibson. The latter collected 226 cases of primary enterorrhaphy with 58 deaths, mor-

tality 26%. Croft, in 1894, recorded 13 treated by artificial anus; all died. Kendall Franks the year before reported 220 cases gathered from various sources, of primary resection, of which Croft declares but very few belonged to English surgeons. Second, in 1894, published details of three cases of primary resection under his own care. All died. Up to 1883 Reichel could find but 56 recorded cases of primary resection; 29 deaths; 51.44% mortality. Carson from this date to 1887 added 21 more; 8 died, 13 recovered, one with artificial anus or large fistula. Czerny and Hahn, in 1898, set the mortality at 47%, Mickulicz, 33%, Borchard, 36%. McCosh, in 1889, collected 113 cases of primary resection in gangrenous hernia which gave a mortality of 50%. Five years later, the same author recorded three more of the same class, all recovering, in his own service. Ziedler gives the mortality as 49% from primary resection and 74% from artificial anus. Frank, mortality, 48% primary resection, 80% artificial anus. Mady, mortality, 22% primary resection. Wallace, mortality, 25% primary resection, 90% artificial anus. Serré in October, 1893, reported 37 cases of resection in hernia; 9 complete cures; cured after fistula, 8; artificial anus left in one; there were 18 deaths. Madelung, 44 cases resection in hernia, 23 recovered, 53%; 22 cases of artificial anus later closed by suture; there were 8 deaths, 36%. Dr. Bovis recorded 17 cases of resection and anastomosis for same condition before 1889; 10 deaths, 59%; since 1889-1891, 51 cases, 19 deaths, 37%.

Makins, 39 cases resection and anastomosis, 15 deaths, 38%. Bouilly, 29 cases resection and anastomosis, 11 deaths, 37%. Korte, 28 artificial anus, 16 deaths, 57%. Friederichshain, 26 artificial anus, 20 deaths, 76%. Poulsen, 54 artificial anus, mortality 86%. Chaput, 51 artificial anus. Recovered 86%. Chaput, 67 primary jointing. Recovered 46%.

Lockwood's statistics show 88% mortality for artificial anus. In 1894 combined statistics of Czerny, Reidel, Kocher, Hagedorn and Hahn, 64 cases of primary resection, 32 deaths, 50%. Barette's statistics, 49 cases primary resection, 23 deaths, 47%.

Gibson sets down failure of technic as responsible for 13% of deaths after resection.

My own experimental work wherein I was able to verify the cause of death, by autopsy, in every instance, it was proved conclusively that faulty technic was always responsible for the fatal ending. This has been well borne out, too, in my unfortunate first cases of resection in the human being, and my later cases which survived.

Recorded statistics conclusively prove that the operation of primary resection with its larger application has a steadily reduced mortality, in general, much less than the production of an artificial anus, although it is well to remember that an enterostomy of late years is only resorted to in very desperate cases; those in which, as Moyenhau well observes, "resection of the loop and suture of the ends is most satisfactory, but there are not a few patients in whom such a course would be wholly unjustifiable."

These statistics include 96 cases, several with incomplete data. There were 68 recoveries, 21 deaths, in 7 result not stated—mortality general, 30.88. Mortality in end-to-end enterorrhaphy by suture—57 cases; 14 deaths, 25.25. Murphy button, 16 cases, 3 deaths, 20.20. Senn plate, 5 cases, 1 death, 20.00. Connell suture, 4 cases, 0 deaths. Twelve cases of mixed

methods treated. There were 45 females, 32 males, in 19 sex not stated.

The Senn plate was first described in 1889. It was soon discarded as unsatisfactory in gangrenous hernia. Murphy published the description of his metallic double disc in 1894. It has proved unrivalled as a means of jointing for various pathological states of the intestine, but after resection for gangrenous hernia it has been largely set aside as inferior to the suture, the Connell mode of adjustment having the preference with those who are familiar with its technic.

Temporary Evisceration with Lateral Anastomosis in Situ, in Gangrenous Hernia.—In certain cases of gangrenous hernia rather than form an artificial anus or do a resection, some authors have recommended the withdrawal of the suspected loop after relieving the constriction, imbedding it in warm, aseptic dressings and delay for 24 hours or more, in order to determine if the death of the part is complete, or to what limit it may have extended. Although this procedure has been suggested, I am unable to find any recorded cases wherein it has succeeded, nor does it appear to be a means that is without serious drawbacks. A strangulated loop at all approaching the mortified condition is in a paralyzed, crippled state, outside the abdomen the mesentery is placed in a condition of tension with a languid circulation. The endothelial investment of the intestine is endowed with a most exquisite sensibility to irritation; hence, on exposure, it quickly presents evidences of inflammatory changes, loses its gloss and becomes granular. Therefore, even though the intestine were found to have preserved its full vitality, its return to the cavity of the peritoneum after an abode of 24 to 48 hours outside of it, would be quite certain to involve free adhesions and more peril than had it been reduced in the first place. The loss of the serous tunic in the repair and reduction of a healthy intestine, the former seat of an artificial outlet, is, without doubt, a more serious impediment to union and restored function than the temporary spur formed; and reasoning from an analogy we must anticipate the same difficulties from temporary evisceration in gangrenous hernia.

The procedure of Helferich, of anastomosing the healthy intestine on either side above the gangrenous loop, the latter to remain in the wound until the patient has fully reacted, when it is resected has nothing to recommend it. It has all the objections of temporary evisceration; it is a more serious procedure than the formation of an artificial anus without its advantages. The temporary anastomosis will occupy quite as much time as to effect a clean resection jointing and reduction; and in any event involves later, another difficult and dangerous operation. It is at the present time quite generally discarded.

Secondary Resection.—Fecal fistula, artificial anus and physiological exclusion with lateral jointing in gangrenous hernia, all call for consecutive intestinal resection, after the patient has recovered from their immediate dangers. At this stage one would expect that there should be a low mortality, but in resection and jointing, as has been seen, the latest writer on the subject, Gibson, has rated it the same as primary resection. Reichel places the mortality as 37.8, Hartzburg, 27, and Makins, 28.4. Lockwood very pertinently observes that "we must bear in mind that those on whom secondary suture is performed are the rare survivors of a most fatal class of cases; moreover, the successful cases recorded are of fecal fistula rather than gangrenous

hernia." Newman believed that secondary resection was less mortal, but noted that this was only resorted to in those who had survived a most dangerous disease.

Richter, in 1788, first successfully resected the bowel secondarily for gangrenous hernia. Seventy-five years later, in 1863, Kinloch, of South Carolina, U. S., per-

formed successfully the first secondary resection of the bowel in America. It was not for hernia, however, but a gunshot wound, and it appears too, that a small fecal fistula remained for some time after the bowel was resected.

Bouilly and Assaky, up to 1883, could find on record but 27 operations for the closure of artificial anus; 26 after gangrenous hernia; 17 were successful.

In 1881, Rydygier reported 18 cases; in 1882, Madelung 22, from various sources, the same ratio of recoveries noted, as by Bouilly.

In order to ensure the best results after secondary resection, the patient should be in a state to promptly recuperate from the shock of the operation, as little blood as possible should be wasted. A free resection should be made widely from parts the seat of pathological changes. This favors early union and an escape from the dangers of necrosis at the site of suture.

PART VII.

ON THE MODE OF JOINTING THE DIVIDED ENDS OF THE INTESTINE AFTER RESECTION OF A GANGRENOUS LOOP.

Up to the time of the report of my own case of resection of a gangrenous loop—30 inches long—after strangulation, my patient making a prompt recovery, I can find no case on record in which any other procedure was adopted to unite the divided intestine and reestablish the alimentary canal, than by invagination, or end-to-end junction, in gangrenous hernia.

The end-to-end mode of junction appealed to surgeons as the most rational because it restored the direct continuity of the canal. Mr. Thomas Bryant, in writing on the technic of end-to-end enterorrhaphy, and the obstacles in the way, said "he could not conceive anything more difficult than to unite the separate segments of the bowel, one infiltrated and distended and the other patulous and collapsed."

The various mechanical appliances and sutures have, scarcely without exception, in intestinal resection for mortified hernia, been utilized in effecting end-to-end union. But its range of applicability was found limited until Murphy's button was invented in 1894. This contrivance enormously simplified end-to-end junction and greatly reduced its mortality from leakage at the mesenteric border.

Dr. William Evans, of Chicago, in a recent study of the question of stenotic contraction after union or circular enterorrhaphy, denies that stricture ever follows the line of junction. Stricture of a tubular passage only occurs in a permanent form, after an extensive loss of mucous membrane, something entirely absent on reconstructed intestine.

Lateral anastomosis as a substitute for end-to-end enterorrhaphy, after intestinal resection, was first brought to the notice of the profession by Dr. M. E. Connell, another Chicago surgeon, the pioneer in experimental intestinal surgery in America. At the time when he published a description of the suture which bears his name, he called attention to the greater safety and security of lateral anastomosis as contrasted with end-to-end jointing. He claimed for it, an escape from the dangers of leakage at the mesenteric border, in the facility of execution with intestines not corresponding in caliber, and finally the prompt and full restoration of function after this mode of jointing. But his deductions were based, like Lembert's original, entirely on experimental research and on theoretical grounds.

This substitute for jointing, together with his new suture, were rejected for a time by the profession.

From a speculative standpoint, there stood out three glaring objections to lateral jointing. The first was, that it entailed the closure of 4 openings instead of 2; second, it left two blind pouches, or diverticula; third, it forced a deflection of the course of the fecal current from one loop of intestine into another. It would certainly seem to involve a positive disturbance in the physiology of digestion. But, practically, we find nothing farther from the fact. In my first case with a large resection—lateral anastomosis near the distal end of the ileum—my patient, now 4 years since the operation, has gained 30 pounds in weight and has perfect digestion. In my second case the ileum was divided close to the distal end and was laterally implanted on the cecal wall—ileocecal anastomosis lateral. In 2 months my man weighed 15 pounds more than before the operation, and, notwithstanding the functionless state of the ileocecal valve, he has vigorous digestion.

Bidwell, in recording his experience in resection for gangrenous hernia, expresses his belief that lateral anastomosis is much safer than end-to-end.

Mr. Greig Smith did not favor lateral anastomosis, he alleged, "as there is as much time consumed in closing the two ends as is necessary to make a circular enterorrhaphy." As far as function was concerned, he regarded it of little importance, as to the axes of the bowels, "whether they were jointed end-to-end or laterally, the question being quite wholly a practical one."

In 1889, Jessett laterally anastomosed the divided ileum with the cecum, after the excision of a new growth, the patient sinking on the fourteenth day. There are several cases scattered through surgical literature of successful lateral anastomosis after resections for neoplasms; while for unilateral exclusion or mechanical obstruction no operation on the intestinal canal is more common or more effective.

In a recent valuable contribution by MM. Terrier and Gosset it is maintained that in bilateral exclusion of the bowel with resection of the intestine for gangrenous hernia, end-to-end junction with Murphy's button is a great saver of time; but that in the reestablishment of the *tractus intestinalis* lateral enteroanastomosis may be performed with great facility and its functional results are perfect. Reichel has demonstrated that here the diverticula at the ends atrophy and contract. Von Frey, by a series of experiments on animals, pointed out that after 6 months, in lateral anastomosis, the intestinal current assumes a perfectly straight direction. This view is supported by von Haecker, who found that the closed ends have so apposed that the afferent coil will continue in the direction of the efferent. Gibson remarks that some resort to this means to do away with the danger of necrosis of the suture line, as well as to effect perfect union when dealing with segments of uneven caliber.

The special advantages of lateral anastomosis, in cases of gangrenous hernia, are:

First and greatest, it obviates that lurking danger, always present in end-to-end circular enterorrhaphy, viz., consecutive leakage at the *dead space* in the mesenteric border.

Secondly, it secures the jointing of the segment of the intestine in full vascular activity.

Thirdly, it permits of the greatest rapidity and facility of execution.

Fourthly, it completely obviates the possibility of

ultimate annular stenosis or a contracted narrowing of the aperture.

My own experience with this mode of jointing after resection, based on an extended series of experiments on the lower animals, and in two aggravated cases of gangrenous hernia employed after the method of Connell, induces me to recommend it in all cases, as simpler, safer, and more effective than end-to-end union by any of the numerous devices now employed.

On the Technic Employed in Uniting the Divided or Excluded Intestine.—The elements which are essential to success in intestinal resection in gangrenous hernia, besides asepsis and proper preparation, are:

1. Those means which effectively restore the continuity of the intestine and securely wall off the intestinal from the peritoneal cavity.

2. The economy of time.

3. The fullest possible circulation to the traumatized parts.

The Law of Lembert.—The principle laid down by Lembert, that in order to secure the firmest possible adhesions between the divided intestine, it is only necessary to appose their serous surfaces, remains unassailable; but he certainly was in error when he taught that in the introduction of the suture, danger was invited if we carried it through all the coats of the intestine. In fact, the modern stupendous advances in intestinal surgery only began when this precept was cast aside. Senn's celebrated essay in 1889 marked the beginning of the new epoch. The adjustment of his decalcified bone plate required the suture to pass through *all* the coats of the gut.

In the preliminary purse-string suture, in the Murphy button operation, it is a matter of no importance whether the needle pass through all the coats of the intestine or not. In Connell's suture the needle passes in and out through *all* the coats. The mythical objection, that a through-and-through suture necessarily involves a fistulous passage from the mucosum out, has absolutely nothing to support it. The fatal defect in intestinal jointing before Senn's plates were invented was that the peristaltic movement of the intestine began *before* the seroplastic cement was sufficiently organized to hold the ends of the bowel in position; and the sutures being numerous applied, they superficially reduced the vitality of the parts, readily tore out and permitted of a fatal extravasation. Senn's plates impressed one as large and clumsy, but they were strong and resistant; however, their introduction required special skill, they were not time savers, and they were a foreign body; nevertheless, they were a distinct gain over any means in use before their time, because they maintained a firm grip on the ends of the gut and held it in position until union was secure.

Various devices were invented after the Senn plates, but none of them possessed any especial advantage over them until Murphy perfected his wonderful invention, a double disc which not only holds the ends of the intestine securely compressed against each other, but at the same time affords a continuous lumen, takes a bite out of each end of the intestine, finally the machine becoming detached and thrown off by the rectum, when it may be cleansed and immediately sterilized for another bout.

But perfect as this apparatus is, it has many serious drawbacks; it requires both skill and tact to readily employ it to advantage. It must be properly constructed and of such diameters as correspond with the

lumina of the divided intestine. The rim of the button may cut unevenly or it may become clogged with feces. A heavy button, segmenting the small intestine, dropped into the abdominal cavity may cause a kinking of the coil and thus induce obstruction.

Three years ago, Prof. Senn informed me that he had discarded all apparatus and depended on the suture alone. Villard says that in gangrenous hernia, an anastomotic button constructed on Murphy's model should be the method of choice on jointing. Jonathan Hutchinson, Jr., says, on the contrary, he has been working on the statistics of resection of the intestine for gangrenous hernia and had found that when the Murphy button had been used there were only 7% recoveries, and 40% when the direct suture was employed.

On the Mode of Suturing and Suture Materials.—If we discard anastomotic apparatus, what method of suture must commend itself? Jaennell observes that "suture must fulfil two conditions; it must close the wound in the intestine and it must preserve sufficient caliber of the intestine. But it must do very much more than this; it must hold the ends of the intestine firmly together not only until they have adhered, but until they are soundly *healed*. The fatal error in the past was in assuming that after temporary adhesions were formed all danger of subsequent leakage was over. Stanhope Bishop collected no less than 33 different modes of uniting the intestine; to this number, in 1896, the late Greig Smith added 33 modifications or new methods. Next to the Lembert suture, the modification of Czerny, in the past, is the best known, the *suture en etage*, the two or three row suture, the muco-mucous, the muscular and the sero-serous. Its purpose was to give greater firmness to the bond of union and to prevent leakage; but the multiplicity of sutures defeated the object in view in many cases. The Czerny-Lembert suture involved a most trying task; one American surgeon who reported a successful result with it, says "it required from 'three to four hours' to complete the suture of the intestine."

The multiplicity of knots strangle the circulation and favor gangrene. It was believed, however, that the homologous apposition and union separately of the three tunics of the divided intestine insured a more complete and stronger bond than the simple adhesion of the serous surfaces.

Both the Senn decalcified bone plates and the Murphy button, the two best known mechanical expedients in jointing, require the employment of a suture as a preliminary in their adjustment; both entail an infolding or an inversion of the divided ends of the intestine, their serous surfaces only coming into immediate contact when the twin segments of the apparatus are fixed. Senn's discs, in its application, were the first to involve a departure from the law of Lembert in effecting an intestinal anastomosis, as a fixation suture in its insertion, passed *through all the coats* of the intestine. The results following the employment of Senn's plates were highly unsatisfactory in anastomosis after resection in gangrenous hernia.

The Connell Suture.—Dr. M. E. Connell, who was a collaborator with Prof. Senn in his early experimental work on the intestines of animals in Milwaukee, in September, 1892, published the technic of a suture which he had devised as a means of joining the divided intestine by end-to-end enterorrhaphy or by lateral anastomosis, when required for any condition whatever. Like all original investigators, his experience was con-

fined to animal experimentation. In his essay he limited its application to end-to-end enterorrhaphy, but one of his pupils, a talented young physician, Dr. A. D. Davidow, informed me that Connell subsequently insisted that the fullest measure of usefulness and security for his suture was best realized in the lateral jointing of the intestine, as his mode of dividing the bowel and treating the mesentery were important factors in success. Connell claimed for his suture, that it involved the employment of no foreign body, that it could be introduced as quickly as any description of a disc, that its material—a round needle and a silk thread—could be found in every household, and that used by an experienced hand it is a simple, safe, and effective expedient.

Mr. Greig Smith, in the last edition of his work published in 1896, in noting some of the later devised sutures, mentions Connell's, but said as there were no recorded cases of its use, he would not describe it. In the autumn of the same year, after a thorough testing of it on the lower animals, with the able assistance of Dr. Davidow, it was my good fortune to employ this suture for the first time on a human being, my patient being a young Chinaman with gangrenous hernia, requiring the removal of 30 inches of the intestine; speedy recovery following. My later case, in which 19 inches of gut were removed, my patient being able to return to his position as a shipping clerk just 6 weeks from the time of operation.

The suture of Connell embraces a radical departure from all others.

1. In resection of gangrenous intestine, lateral anastomosis is preferred; this was employed in both of my cases.

2. It is a continuous, longitudinal suture, silk always preferred.

3. The suture passes through all the coats of the intestine.

4. The suture is everywhere turned in except where the knots are tied.

In gangrenous hernia requiring resection and jointing, it is, *par excellence*, an ideal method, in extra or intraperitoneal cases.

No description of apparatus can be applied with greater ease or economy of time; but there are situations within the abdomen where the Murphy button may be more expeditiously employed.

Used in lateral anastomosis, its greatest utility is realized through the manner in which the full vascular supply is maintained, the large aperture which is made and the firm bond of union secured.

It is certainly my conviction that when the technic of its application is better understood, it will be accepted by all surgeons as the simplest and safest of any suture yet devised.

In a recent contribution on a valuable contrivance for holding the intestine in position while doing an end-to-end jointing, Dr. H. Lee, of Chicago, says that he prefers the Connell suture above all others, as when properly inserted it is followed by ideal results.

Suture Material.—Suture material for intestinal work is an important element in technic. Two varieties of suture are generally selected; the absorbable and the nonabsorbable. With many, catgut has had the preference, because, when properly prepared, it will maintain the divided parts in contact sufficient time to ensure union, and later, undergo complete resorption. But properly prepared, fresh catgut is not always

accessible; some claim that its complete sterilization is impossible without impairment of its integrity. At all events, it requires a spear-pointed needle to carry it, it entails an excess of trauma in its introduction, it may often stretch and slip at a dangerous stage, and permit a fatal leakage from the bowel; in a word, in intestinal surgery, it is the general consensus of surgical opinion that it is not the most desirable material.

The silk suture possesses the most necessary qualities for an intestinal suture.

1. It is the strongest and most durable; these are the primary essentials. It is true that it cannot be effectively sterilized, but this is a consideration of secondary importance if it count for anything at all, in intestinal jointing, as anything like an aseptic wound here is a myth, for by the most approved and effective methods here employed, the widely divided ends of the intestine are left exposed to free irrigation by stagnant, decomposed feces, which immediately begins as soon as the continuity of the intestinal canal is re-established and the enteric contents begin to move on.

2. We can employ a fairly fine silk suture which may be introduced with a round cambric needle, one which acts on the principle of the wedge and divides the walls of the intestine without cutting.

The ultimate course of the silk suture after introduction is not known; it probably rarely, if ever, is absorbed; it either becomes imbedded in the tissues or is thrown off by the intestinal canal. In dogs killed six months after the silk sutures were employed on the intestine, I have found them buried under adhesions, entirely unchanged.

Tamponage and Drainage.—Everyone who has operated for strangulated hernia is aware that even after the constriction is removed and the stricture is relieved, the reduction of the intestine is often tedious and difficult; after the resection of a gangrenous loop and anastomosis by an apparatus or the suture, the difficulty is greater yet; the mass is bulky and awkward to manipulate, a considerable degree of force must be employed to return the overdistended coils, and great caution is needful that the jointing is not disturbed. Hence the reason why a large, free opening must be made up through Poupart's or Gimbernat's ligament, that no undue strain be put on the herniated bowel.

In all these cases a tampon drain is necessary. The Mickulicz gauze or cigarette tampon is probably the best. There is always some serous oozing, and there may be some leakage. My practice has been to pass a drain down to the site where the intestine is joined, and not around the bond of union. Immediately on the reduction of the united loop temporary adhesions wall it off from the cavity of the peritoneum, but the gauze drain establishes and maintains a passage from this, now extraperitoneal loop, with the exterior of the body. If everything goes well, the tampon is not removed until the second day. By this time, intestinal paresis will have passed off, and peristalsis have begun. At this stage there may be a varying degree of leakage. Gentle irrigation is now practised, and the wound is again freshly tamponed with a small gauze drain. In both of my cases it continued for a week, and within three weeks the wounds had solidly closed.

Ziedler observes that "the most frequent cause of death in the cases of gangrenous hernia is leakage at the site of suture with resulting peritonitis; hence we should always tampon so that a way of escape is freely provided."

Ventral hernia we might expect after large incisions necessary in resection wherein so large a breach must be made in the abdomen, which later closes in by scar tissue; but it has not occurred in my two cases, nor do statistics show that it is a frequent sequela. Probably the adhesions which environ the reduced intestine tend to fix it, so that its subsequent descent is impeded and recurrence prevented.

Albumin Transformation and Sugar Excretion.

—Rumpf (*Deutsche Med. Woch.*, Oct. 4, 1900) reviews the work which has been done in the attempt to prove that **fat may furnish sugar**. No one has yet demonstrated this satisfactorily. It has been generally an accepted statement that it is possible for sugar to be formed from albumins, and that so long as the sugar excreted was not more than 6 or 7 times greater than the amount of nitrogen excreted the whole amount of sugar may reasonably be thought to be derived from albumins. Rumpf and his assistant experimented with dogs, first accustoming them to a special diet which contained only a small amount of albumin but a large amount of fat, and then producing phloridzin glycosuria. They determined the sugar nitrogen excretion through periods of 5 days each, and demonstrated that in one of these periods the average sugar excretion was 8.9 times greater than the nitrogen excretion. During this period the relation of nitrogen to sugar was as follows: On the first day 1:9.7; on the second day 1:7.1; on the third 1:8.5; on the fourth 1:9.9; on the fifth 1:12.2. He decided, therefore, that the sugar formed could not have come entirely from the albumins, and that some of it must have been produced by fats. There was no evidence of a nephritis which could have caused retention of nitrogen. Also he in-

vestigated the excretion of SO_2 and P_2O_5 . He found that there was no relative increase in the phosphorus excretion, a fact which was against the theory of Blumenthal, that albumin, which is especially rich in phosphorus, is destroyed in diabetes. [D.L.E.]

Dysentery as a Human Disease and Its Cause.

—Krusse (*Deutsche Med. Woch.*, Oct. 4, 1900) directs attention to the fact that **dysentery** is constantly endemic in certain regions in Germany, and at times has broken out in large epidemics; in the last few years it has been increasing in frequency until, in 1898 and 1899, there were in one locality 100 fatal cases, and in the year 1899 alone, in Barmen there were 600 cases with 66 fatalities. In one region in which there were 300 cases with 30 fatalities he made extensive bacteriologic studies. In the first place he found in the fresh dejections no amebae, but small clumps of pus which contained practically only one form of organism. This was a short plump bacillus. Its cultural peculiarities were almost the same as those of the bacillus of Shiga and Flexner, it being chiefly distinguished by the fact that it was not motile. Agglutination-tests with the blood-serum of patients who had been ill for more than 7 days with dysentery showed regularly an agglutination in a dilution of at least 1:50, and in some instances in dilutions as great as 1:1000. The serum of healthy persons very rarely showed such action in a dilution greater than 1:10 or 1:20. Other intestinal bacteria were tested, but they showed no agglutination. The dysentery apparently caused by this bacillus also differed from that described by Shiga and Flexner in that the chief gross anatomic change consisted in a widespread pseudo-membrane formation on the mucous membrane of the colon. [D.L.E.]

The Duty of the Physician to the State.—The recent utterance of a Philadelphia judge to the effect that it would be better that a patient should die rather than that a physician should neglect a judicial summons, has stirred up the lawyers as well as the doctors. The physician's standpoint has already been given editorially in the JOURNAL, but it may be of interest to note how it is viewed by the legal profession. The *New Orleans Times Democrat* has taken the trouble to obtain the opinion of a number of leading members of the Bar and judges upon the course of the judge, and their unanimity in condemnation of the opinion is striking. The expressions, "unreasonable and arbitrary," "not ruled by the ordinary law of common sense," "absurd," "inhuman," "brutal in its effects," are some indications of how the judge's action and statements are appreciated by his legal brethren. If he is at all sensitive to public opinion he will not be likely to repeat his action, which one can hardly believe was prompted by any deliberate consideration of the facts. Judges, however, are the men who, more than others, should guard their speech and action from any suspicion of inconsiderateness, and if they make mistakes such as that of this Philadelphia jurist, must suffer for it accordingly in public and professional estimation.—[*Journal of the American Medical Association*.]

Contribution to the Study of the Connective Tissue Tumors of the Kidney of the Adult.

(*Gaz. Heb. de Méd. et de Chirur.*, February 3, 1901, 48me Année, No. 10; *Paris Thesis*, 1900-1901, No. 60.) According to Bahaud the embryonal connective tissue neoplasm is represented in the kidney by sarcoma. Sometimes round-celled sarcoma is found, again the spindle-celled variety is met with, quite often the two elements are united in variable proportion, and sometimes myxosarcoma has been observed. From the point of view of its structure, a great development of the connective tissue ground substance is sometimes noted which may go on to the production of a fibrosarcoma. The vascular element is often very well developed which accounts for the frequency and the volume of the blood cysts. Sometimes smooth muscle fibers are found which have no importance from the viewpoint of the histologic value of the tumor. The adult connective tissue tumor is represented in the kidney by fibroma and lipoma. These tumors spring from the interstitial connective tissue of the organ, in the neighborhood of the hilum, beneath the capsule, or in the fibrous capsule itself. Other tumors of this nature spring from the suprarenal capsule or from suprarenal rests. [J.M.S.]

The Report of the Committee on Anesthetics.—

The ninth and final report of the anesthetic committee of the British Medical Association, appointed 10 years ago to inquire into the relative safety of various anesthetics, the best methods of administration and of restoration, has recently been published. The report is based upon an analysis of 25,920 cases from hospital and private practice, of which 13,393 were cases of chloroform-anesthesia, 4,595 ether, 2,911 nitrous oxide, 2,071 gas and ether, 678 A. C. E. mixture, and the balance various combinations of, as, for example, mixtures of chloroform and ether, chloroform followed by ether, and vice versa, nitrous oxide and oxygen, etc. Although an immense amount of time and energy have been unselfishly expended by the committee in the pursuance of these investigations and the collaboration of these statistics, the report is, on the whole, disappointing. Of the 35 conclusions of the sub-committee but few have been drawn upon a strictly numerical basis, the majority are expressions of opinion the value of which depends upon the judicial capabilities of the committee and many are negative in that no conclusions are warrantable. For purposes of analysis and comparison the total number was divided into two general classes, the uncomplicated and the complicated, and the latter subdivided into (1) cases with minor complications, (2) cases of anxiety, (3) cases of danger, (4) cases of death. As in such a large majority of cases chloroform or ether was the anesthetic employed, "the conclusions of the report frequently resolve themselves into various phases of the chloroform vs. ether controversy." As to the relative safety of these anesthetics, taking into consideration only those cases of danger (including death) for which the anesthesia was held wholly responsible, under chloroform there were 78 or 0.582% as compared with 3 under ether, or 0.065%. The observation is made that "although (excluding nitrous oxide) ether may be accepted as the safest routine agent, certain circumstances determined by the state of the patient, the nature of the operation, etc., may render the use of some other anesthetic or combination of anesthetics both safer and easier." The committee were able from the clinical evidence to draw no conclusion as to the best method of administering ether; and as to chloroform, we are told that while no method is free from danger, inexperience on the part of the administrator rather than any particular

method must be held accountable for the occurrence of complications, fatal or otherwise, in the great majority of cases. As to the best method of restoration, here again the committee humbly confess their inability to draw any conclusion from the material at their disposal. Many of the conclusions that particularly concern chloroform-anesthesia are simply confirmatory of opinions in vogue for some time past. The alarming symptoms are those of primary circulatory failure; many have, however, been traced to imperfect anesthesia. Prolonged vomiting and circulatory depression are more common after chloroform than ether, while respiratory complications, though occurring with equal frequency under ether and chloroform, were apt to be "transient and trifling" after ether and "grave and persistent" after chloroform. Perhaps the most practical conclusion from the standpoint of the anesthetizer is the last, namely, that by far the most important factor in the administration of anesthesia is the experience of the administrator and that in many cases the anesthetization so completely transcends the operation in gravity and importance, that it is absolutely essential to consign that duty to an experienced anesthetizer.

The committee were unable to throw any light upon two important subjects: the safest method of administration and the most reliable method of restoration. Whether or not the committee in charge could have used to better advantage the mass of clinical evidence which passed through their hands we are not in a position to judge, suffice it to say that they have contributed little if anything to the knowledge of anesthetics already acquired. That ether is the safest anesthetic for routine work; that the alarming symptoms of chloroform-narcosis are due primarily to circulatory failure; that no method of administration of chloroform is free from danger; that, excluding infancy, the complications and alarming conditions of narcosis increase *pari passu* with advancing age; that the tendency for these complications to occur increases *pari passu* with the gravity of the operation; these, as most of the other conclusions, are but confirmatory of long-established views. As an exception to this general statement we might call attention to their observations on the respiratory complications of anesthesia. In their experience the complications that occurred under ether were mostly of a trifling and transitory nature, while those occurring under chloroform were grave and persistent.

The Diagnosis of Malaria from the Standpoint of the General Practitioner.—From the standpoint of accuracy, simplicity, and practicability, the diagnosis of malaria by determining the presence of the specific parasite in the blood must be looked upon as the most approved clinical method, perhaps outranking every other clinical microscopical test in point of usefulness. The vague expression of such an inaccurate term as "a touch of malaria," so commonly employed by many physicians, finds its origin chiefly in the lack of more constant and systematic blood-examination in every suspected case, and in part to the indiscriminate and hasty use of quinin as a therapeutic test. Many of these periodical ailments, loosely designated "a touch of malaria," undoubtedly subside quite independent of the drug when it is administered. Aside from the gross misrepresentation of statistics brought about by such a method, the life of the patient is sometimes jeopardized. The question of immediate recognition of such a condition as a deep-seated suppurative process presenting symptoms resembling those of malaria, is often of vital importance for the early establishment of a plan of treatment. The delay caused by the administration of quinin, in order to exclude malaria, is, as a rule, inexcusable, for we have at our command that more reliable resource, the microscopical examination.

It is well known that malaria may sometimes coexist with some other febrile condition, for instance, enteric fever. In such a case, of what possible value is the administration of the therapeutic test? In the event, however, of malaria not complicating the condition the harm that might arise is manifest. The similarity of malarial fever to many other diseases indicates the necessity of differentiating by a search for the plasmodium. Under exceptional circumstances the therapeutic test has its place, but never when the clinical method can be pursued. The advantages of the latter are so apparent as to hardly require comparison. A single droplet of blood will not only determine the presence of the disease, its type, or combinations of types, the relations of the time of examination to the time of the paroxysm, with some degree of certainty; but will also indicate the manner of administration of our therapeutic measures, and the necessity of proper isolation to prevent the spread of the disease by means of mosquitoes. The early recognition of some of the pernicious types without the aid of the microscope is so difficult that the most expert clinician may err. From the prognostic standpoint, early and vigorous treatment constitutes in many instances the only means by which life may be saved. The negative value of the clinical test is equally important. It is a well-known fact that considerable experience is necessary to distinguish some of the forms of the malarial parasite, especially the hyaline, non-pigmented bodies; but this should in no way constitute a valid excuse for its non-employment. In the present state of our scientific

knowledge a microscope, slides and cover-glasses should constitute a part of the armamentarium of the well-equipped, practical physician.

Symptoms of Disseminated Sclerosis Occurring in Malarial Infection.—Dr. William G. Spiller has published an interesting paper (*American Journal of the Medical Sciences*, December, 1900) on this subject, based upon a case which occurred in Dercum's clinic at the Philadelphia Hospital. The patient was a man who had had syphilis and who became slightly hemiplegic on the right side in 1890. The hemiplegia was transient, but five years later the patient began to have headache, vertigo, drowsiness and diplopia. Left transient hemiplegia also occurred. The left leg remained ataxic, the Romberg symptom was present, and there was intention tremor of the left upper extremity. The patient had vertical nystagmus and scanning speech, and the knee-jerk was increased on the right side, on which side also there was ankle clonus. He presented a somnolent appearance, and died from an intercurrent diarrhea nine years after the beginning of his disease. At the autopsy the right crossed pyramidal tract was found sclerosed, but not extensively so. An interesting finding was enlargement of the spleen. No true disseminated sclerosis was found anywhere in the central nervous system, but numerous small recent hemorrhages were found in the left paracentral lobule and other parts of the cortex. Dr. Spiller was not able to discover any distinct syphilitic lesions, such as proliferation of the walls of the bloodvessels. The small bloodvessels throughout the brain and cord were filled with the malarial parasites. The patient had not presented, so far as was known, any of the ordinary symptoms of malarial infection. The identity of the parasites was established by Dr. A. Stengel and Dr. W. S. Thayer.

Dr. Spiller points out that the malarial parasite, of the estivoautumnal type, may exist as a larvated form for an indefinite time, and he includes his case among cases of this variety. He presents the literature of the subject, from which we learn that symptoms of a pseudosclerosis have been observed by some of the best investigators in cases of undoubted malarial infection. Among these observers are Triantaphyllides, Forti, Angelini, Bignami, and Bastianelli. The symptoms in some cases have disappeared under antimalarial treatment. Dr. Spiller's case has a unique importance as being the first in which the malarial parasite has been demonstrated postmortem in such a long-standing case, although the plasmodium had been observed during life in some other reported cases. The facts that Dr. Spiller's patient had had syphilis, and that some of his earlier symptoms, such as transient hemiplegia, diplopia and headache, strongly suggested a syphilitic infection, have not been ignored in this study of the case, but Dr. Spiller reports that distinct syphilitic lesions were not discovered.

The Treatment of Spina Bifida.—When one considers that the large majority of cases of infants suffering from spina bifida run a rapid course to death from rupture and convulsions, or spinal meningitis, it is gratifying to observe the good results being obtained by surgical interference in these hopeless cases. Palliative treatment, the seton, and the injection of Morton's fluid have all been tried and have accomplished practically nothing. A spontaneous cure is of the rarest occurrence. Restoration of the cord, when present in the sac, to the spinal canal, and excision of the sac, although at first productive of a large mortality, certainly seem justifiable in the light of the necessarily fatal nature of the disease and the infinitesimal chances of spontaneous cure. The method of treatment which was strongly urged by Bayer, Robson, and others has been perfected, and good results are frequently being reported. Mr. Nicholl, in the *Lancet* of March 3, adds to his other contributions on this subject a brief report of three cases of young infants operated upon for cervical spina bifida, and returned to their homes the same day under the care of a nurse. These infants all made complete recoveries, and the wound in each case healed by primary union. Of course, the surgical treatment of spina bifida occurring in the cervical region is much more hopeful than in the forms met with in the lower portions of the spine, and the results which Nicholl has had ought certainly to encourage the surgeon to further effort in the treatment of this distressing condition.

Surgeons in discussing this subject as well as in treating these cases, do not, as a rule sufficiently distinguish the several forms of spina bifida. The simple meningocele, in which there is no portion of the spinal cord included in the sac, is naturally much more easily cured, and with far better results, than the meningo-myelocele, in which the sac contains portions of the undeveloped spinal cord. An excision or obliteration of the sac in this latter form cannot cure the child in any sense because it leaves the patient permanently crippled. Some cases are even left paraplegic.

Recent Notes on Plague.—We are indebted to Captain R. H. Jackson for an original communication of great interest in his Notes on Plague at the General Plague Hospital, Balgaum, India, 1899, which appeared in the *Dublin Journal of Medical Science* for February, 1901. The spread of this disease is favored by those arch-enemies of health, overcrowding, deficiency of ventilation and sunlight. The poorer classes suffer greatest from its ravages. Infection is caused either by inoculation, or through the digestive tract, or the respiratory organs. Two distinct forms of plague are described: Pestis major (severe or ordinary plague); and Pestis minor (abortive or larval plague). The varieties of the Pestis major are: (a) Bubonic; (b) pneumonic; (c) septicemic; (d) pyemic; (e) local inoc-

ulation. It is interesting to follow the course of an average attack of ordinary bubonic plague, as described by Dr. Jackson. The period of incubation is given as from 3 to 7 days; the period of invasion, or the prodromal stage, varies greatly in length. Sometimes there is a sudden onset, but usually 24 to 48 hours pass before the disease shows any of its characteristic symptoms. During this prodromal stage the patient has chills with fever, and suffers from lassitude, weakness, headache, vertigo and vomiting. Then follows the stage of bubo development, with a characteristic staggering gait, great restlessness and tremulous speech. The temperature at this time is 104° F. or higher. The pulse is full and quick and averages about 130; the tongue is typical. It is dry, granular, velvety, with yellow fur and a bright red margin. The face is anxious and pallid and the conjunctivæ are deeply injected. The diagnosis at this stage is easy. The buboes or glandular swellings, extremely painful, develop with great rapidity in the groins, axilla or neck. The bowels are usually constipated. There is generally a fall of temperature and pulse-rate with the appearances of buboes, and this usually occurs on the second or third days of the disease. With this remission the patient appears much improved, but in 52 hours there is a return of the fever, which ranges between 103° and 105° for 7 days, when the bubo has become developed. In 10 days the temperature and pulse-rate drop gradually to normal. The emaciation and exhaustion are extreme, and the great danger of heart-failure still threatens. A protracted recovery, usually occupying two months, may now be expected, should the patient be fortunate enough to avoid the many sequelæ of the disease. Among these may be mentioned cardiac syncope, probably induced by the action of the toxins upon the heart-muscle. Hemorrhages are common and are regarded as most unfavorable symptoms. Pregnant women usually abort, and there were but two exceptions to this general rule in Jackson's series of cases. Peritonitis, jaundice, retention of urine, mental complications and hyperpyrexia, are common. The eye-complications are frequent. In the early stages the conjunctivæ are congested, but with the appearance of the bubo this congestion may disappear. In the later stages severe conjunctivitis, with iritis and ulceration, may lead to total loss of vision. As to treatment, it is comforting to know that inoculation with Haffkine's prophylactic serum has proven of great value. Fifteen per cent. increase in recoveries followed its use. Furthermore, the value of this as a preventive treatment is unquestioned, and a comparatively small number of plague cases occurred among the inoculated. In the 298 cases treated in the Balgaum Hospital there were 183 deaths, a mortality of 61.4%. Plague is clearly one of those dread diseases which by improved methods of sanitation may by its disappearance mark an epoch in preventive medicine. It is an object-lesson of great magnitude.

Hereditary Tuberculosis.—Since Hauser's excellent study of hereditary tuberculosis, in which he reached the conclusion that there were really no satisfactory instances on record of the transmission of tuberculosis from parent to child, excepting in a few cases in which the mother was suffering from miliary tuberculosis during pregnancy, it has been rather the custom to discredit the influence of heredity upon the development of the disease, and particularly to discredit the possibility of infection from the father before birth. In view of the beautiful studies that have been made in certain hereditary forms of nervous disease in which sometimes as many as six generations have been traced, and elaborate family trees prepared (we have particularly in mind Huntingdon's chorea), it seems strange that similar studies have been so rarely undertaken for tuberculosis. It is therefore with considerable satisfaction that we call attention to the recent article of Edwin Klebs (*Münchener medicinische Wochenschrift*, January 22, 1901).

He gives two elaborate family trees, the first including five, and the second six generations. It seems desirable to give briefly the general data concerning these two families.

Concerning the original pair of family "A," dating from 1757, there is no information excepting that the father died at the age of 81. Five children were born, of whom four died of tuberculosis, and the fifth is doubtful. Of these five children, one, a chronic drunkard, married and had eight children, of whom five died of tuberculosis and the infection of the others was doubtful. One of these five, a woman, who died at the age of twenty-five of tuberculosis, married, and had two children, both of whom died in early life of tuberculosis. Two of the doubtful males married, one having three children, two of whom died of tuberculosis; but the other three had five children, all of whom are at present healthy. The other doubtful male married and had two male children; both were married, one to a woman who had already been married to a tuberculous man, and had had one tuberculous child. The eight children of her second marriage, however, were all healthy.

The second ancestral pair, also dating from 1757, had two descendants, one dying of tuberculosis. The latter had two children, one of whom was married twice, and had six children, all dying of tuberculosis; but three of these six married and had three sets of children—three, three, and one, all of them at present healthy. The other married and had five children, four of whom were certainly tuberculous. Four of these five married, one having a tuberculous child, who also had a tuberculous child. Another had one tuberculous child. His widow afterward married one of the healthy descendants of family "A," and had eight healthy children. Another marriage resulted in one doubtful child, and the last was sterile.

From the study of these tables and some other in-

stances that he has observed, Klebs reaches the conclusion that tuberculosis in the father is ten times as dangerous as tuberculosis in the mother, and that if both parents are tuberculous, all the children will certainly be so. In the two families in which the disease was traced for five generations or more, there were fifty-five children, of whom thirty-three were tuberculous, and twenty-two were apparently free. That is, more than 50% of the children were infected. In addition to this, many of the marriages of these children were sterile, showing the disastrous effects upon the race of tuberculosis in the parents.

No Universal Language for Science.—Of all the men who have yearned for a common tongue the men of science perhaps have yearned the most. Medical scientists have certainly as good cause as any others to wish that there was a universal language. Diversity of tongues is an obstacle to science, and the Tower of Babel was the first barrier to the rapid diffusion of knowledge. Considering these facts, it is rather curious to note that Hermann Diele, in a recent number of the *Deutsche Revue*, says that he has no faith in the scheme of a universal language, and that such a language would not be of much value except in commerce, and not much even there. Diele says that Latin is the only language adapted to universal use (just as it was in the Middle Ages), but he evidently believes that the revival even of Latin for such a purpose is only a Utopian dream. He thinks that the agitation for a universal language for the use of the learned has subsided of late years. French seemed to take the lead for a century or two after the time of Richelieu, but it certainly does not hold it now in competition with English and German. Diele thinks that an exclusive patriotism now actuates the several great nations of the world, and reacts against foreign languages. This evidently is true of English, French and German, and there is no prospect of this spirit diminishing. This whole subject is of direct personal concern to medical scientists, for it means that they must continue to cultivate not one but several foreign tongues. Of recent years, indeed, Italian and even Spanish have assumed great importance as languages of science. From the medical standpoint some of these facts are to be deplored, for medical science now demands nearly all a man's time and energy without leaving him much for the cultivation of foreign languages. Moreover, the command which a man acquires over a foreign language when he pursues it merely for the acquisition of scientific facts, is usually not sufficient to give him much facility or pleasure in it. He in no sense becomes a skilled linguist. No one knows this fact better than the medical toilers who delve in German and French. But there seems to be no prospect of a remedy for the polyglot evils of our day, as the following figures, compiled by Carnac, the English statistician, clearly show:

DATE.	ENGLISH	GERMAN.	RUSSIAN.	FRENCH.	ITALIAN.	SPANISH.
	Millions.	Millions.	Millions.	Millions.	Millions.	Millions.

A New Therapeutic Journal.—Beginning about the 1st of May The Medical Journal Union, limited, of this city, will issue a new medical journal to be called the *Therapeutic Monthly*. We are glad to announce that this new journal will be under the editorial care of Professor James Tyson, who will have as his associate editor Dr. Thomas L. Coley. The *Therapeutic Monthly* will have absolutely no connection with any pharmaceutical or drug firm, but will be an entirely independent journal, devoted to the interests of its readers alone. It will contain original papers by therapeutists of recognized reputation, abstracts of therapeutic literature, and editorial matter relating to therapeutics in general. It will consist of 40 pages each month, of the size of the PHILADELPHIA MEDICAL JOURNAL. We believe that the profession will welcome this new monthly, which promises to meet accurately and conscientiously the wants of practitioners in a particularly changeable and difficult field. The character and attainments of the editor are guarantees that these wants will be adequately met.

An Interesting Case of Self-inflicted Injury of the Urethra and Bladder.—Sianoshensky (*Vratch.*, Vol. 22, No. 2) reported before the Society of Physicians of Kiev the case of a peasant woman, who suffered from pruritus vulvæ and, by the advise of some neighbors, applied garlic. Not obtaining any relief, she cut the urethra with a small knife and continued these applications. There still being no relief, the bladder was cut in a similar manner, and the application of the garlic kept up. This was followed by complete recovery from the pruritus, but a condition of incontinence was established for which she sought medical advice. On examination, both the urethra and the neck of the bladder were found severed with the edges of the wound gaping. A plastic operation was performed, and the woman made a rapid and complete recovery. [A.R.]

Soft Chancre Treated by the Cautery.—Zydlovitz (*Gazeta Lekarska*, December 16, 1900), treated 26 cases by Andry's method, which consists in holding a Pacquelin cautery at a distance of from 3 to 4 mm. from the ulcer. The heat kills the virus, and the chancre is transformed into a simple granulating ulcer. The results obtained by the author are all that could be desired. Not in a single case did adenitis or any other complications follow. The injection of a 2% solution in the neighborhood of the chancre was found to produce complete anesthesia. It was also observed that by applying the curet to the floor and edges of the ulcer before applying the cautery, recovery was greatly hastened. An application of the cautery for one minute will destroy the chancre at a single sitting. The subsequent treatment is the same as that of a simple ulcer. [A.R.]

Reviews.

The Practice of Medicine. A Textbook for Practitioners and Students, with Special Reference to Diagnosis and Treatment. By JAMES TYSON, M.D., Professor of Medicine in the University of Pennsylvania, and Physician to the Hospital of the University; Physician to the Philadelphia Hospital; Fellow of the College of Physicians of Philadelphia; Member of the Association of American Physicians, etc. Second edition, thoroughly revised and in parts rewritten, with 127 illustrations including colored plates. Philadelphia: P. Blakiston's Son & Co., 1900. Cloth, \$5.50.

The many years of experience in the teaching of the practice of medicine to students that have accumulated in the lifetime of Dr. Tyson ought to result in the production, out of that experience, of a most valuable textbook to the general practitioner as well as to the student. The verdict of the profession is in favor of Dr. Tyson's book, since, in the space of four years, the first edition has been exhausted and a second edition made necessary. Dr. Tyson's reputation is that of a practical and conservative teacher, and those who learn from him may be sure that they will not be led astray by recommendations to adopt new methods merely because they are new; but rather that new methods are recommended because they have been tried and not found wanting.

The special department of medical investigation with which the author's name is habitually associated is that relating to diseases of the kidneys and the examination of the urine. And here we find a concise and practical exposition of the facts relating to the diseases of these important organs. We think that a more precise statement of the author's own views concerning the nature of cylindroids would have been appreciated by Dr. Tyson's many students.

It would be beyond the limits of the space allowed for a review to treat of each section of the work separately. But we may mention two points on which, like the significance of cylindroids, the profession in general would be pleased to have a more definite statement from the author. These are, first, the value of antitoxin in the treatment of diphtheria; and second, the diagnostic value of lumbar puncture. It would also be of value to have a tabular arrangement of the differential points in the diagnosis of organic and hysterical hemiplegia. The chapter on tuberculosis is very complete and admirably arranged, and the section on the gonorrheal infection is very timely and in the right place.

In revising the section on the diseases of the nervous system, the author has had the assistance of Dr. William G. Spiller. The chapter on general symptomatology will serve as an excellent model for the investigation of nervous diseases. The neuron theory of the composition of the nervous system is set forth in language devoid of technicalities and is admirably adapted to the needs of the general practitioner. [J.M.S.]

The Treatment of Fractures. By CHARLES LOCKE SCUDDER, M.D., Surgeon to the Massachusetts General Hospital, Out-patient Department, assisted by FREDERIC J. COTTON, M.D. Second Edition, Revised. With 611 illustrations, 8vo, pp. 457. Philadelphia and London: W. B. Saunders & Co., 1901.

This book is conspicuously attractive because of the unusual number and beauty of its illustrations. Half-tones, skiagraphs, tracings from skiagraphs, and diagrams crowd its pages. A good many of these pictures have comparatively little real practical usefulness, but they are worthy of study by the scientific student of osseous lesions.

The author's method of presenting the subject shows originality, and as a result his book has a fresh flavor, which inspires the reader's interest. There is, however, little originality in the methods of treating fractures. Indeed, the dressings are unusually complicated and cumbersome. This is probably due to the author's familiarity with the recog-

nized methods of his seniors in the Surgical Department of the Massachusetts General Hospital. An illustration is seen in his statements that a patient with a fractured femur should always be anesthetized before putting the thigh up permanently, that about one hour will be consumed in applying the fracture dressing; and that an extension apparatus, an external axillary splint, a ham splint, coaptation splints, and sandbags are to be employed in the treatment of this usually not very troublesome injury. It is little wonder that the patient requires general anesthesia. One would think that the surgeon and nurses would need general stimulation to stand the strain!

The title is scarcely just to the work, because the volume is much more than a treatise on treatment. Many pages are devoted to the pathology and diagnosis of fractures. In the discussion of fractures at the elbow, some twenty odd pages are occupied by these matters before the treatment is taken up. In fractures of the lower end of the radius, about a dozen pages are used in a similar manner; and, in the chapter on cranial fractures, eighteen pages are given up to these preliminary details.

The more recent improvements in fracture treatment are mentioned in an almost too cursory manner. A special chapter towards the end of the volume is, for instance, devoted to the use of gypsum in fractures, instead of discussing the use of splints made of this material and gauze in the sections devoted to special fractures or in a general statement at the beginning of the work. This circumstance gives one the impression that the author prefers wooden splints to the perfectly fitting plastic splints which are becoming the preference of so many surgeons of today. Again, the operative treatment of cranial and other fractures is scarcely more than mentioned.

The book nevertheless contains many practical suggestions which are often overlooked by practitioners treating fractures. Some of these suggestions are novel; many are none the less valuable, though old.

Within recent months American surgeons seem to have felt a renewed interest in the treatment of fractures, for Scudder and Hopkins have published large books on the subject and Estes and Roberts small ones. This is a hopeful sign, for these lesions are important and are often badly treated. [J.B.R.]

The Treatment of Fractures. By W. L. ESTES, A.M., M.D., Surgeon-in-Chief of St. Luke's Hospital, South Bethlehem, Pa. 8vo, illustrated, cloth, pp. 216. New York: International Journal of Surgery Company.

This volume has the same title as that just noticed, but it is physically and scientifically of a different type. It is plain in appearance, small in size, and illustrated by cuts which are far from artistic in appearance. The abundance and beauty of Scudder's illustrations are missing, though the figures introduced serve to give, as a rule, the information desired by the author.

Examination of the volume soon makes it evident that the author is speaking from personal experience in the treatment of fractures and that he has not been bound by surgical traditions, or the older writers and teachers. He speaks as if he had made good use of his opportunities to study traumatism of bone, and had not failed to draw his own deductions and formulate his own methods of treatment. His frequent employment of plastic splints of gypsum, and of mechanical devices applied directly to the bone after incision of the soft tissues, and his willingness to split open the whole perineum in bad fractures of the pelvis show the thoroughness of his appreciation of modern surgical principles.

Dr. Estes lays perhaps more stress than most surgeons on the necessity of verifying with the Röntgen-ray the apposition of fractures after reduction, and in some other respects he may have individual views which are not in accordance with the opinions of other writers. In the main, however, his statements will scarcely be challenged.

It may seem invidious to make comparisons between two good books on the same subject, but it is part of a reviewer's duty to do so. In the opinion of the present writer this small book is more up-to-date than Dr. Scudder's handsome big volume, and a better practical guide for the professional attendant on cases of fracture to follow. In both books the authors could with benefit have given more attention to

writing accurate English. Scientific works deserve the same painstaking care in the grammatical structure of sentences as they require in the interpretation of facts. [J.B.R.]

Pulmonary Consumption, Pneumonia, and Allied Diseases of the Lungs. Their Etiology, Pathology, and Treatment, with a Chapter on Physical Diagnosis. By THOMAS J. MAYS, A.M., M.D., Professor of Diseases of the Chest in the Philadelphia Polyclinic; Visiting Physician to the Rush Hospital for Consumption. Illustrated. New York: E. B. Treat & Co., 1901. Price, \$3.00.

It is with mingled feelings of satisfaction and regret that we notice that Dr. Mays has given to the profession in systematic form his well-known views upon "Pulmonary Consumption, Pneumonia, and Allied Diseases of the Lungs." Our satisfaction arises from the fact that we are now able to study the whole work carefully and draw our conclusions as to its value. Our regret is that these conclusions cannot agree with those of the author of the work. His point of view has been developed with painstaking care and unquestioned conviction during thirty years, and he is surely entitled to that respectful consideration which he requests in his preface. To quote the author: "The fundamental concepts of the work may be formulated into the following proposition: 1. That pulmonary phthisis is primarily a neurosis, and that the pulmonary disintegration is secondary. 2. That any agent, influence, or condition which undermines the integrity of the nervous system will engender pulmonary phthisis or some other form of pulmonary disorder. 3. That the only remedies of value in the treatment of pulmonary phthisis are those which appeal to, and act through, the nervous system. 4. That of special value in the treatment of phthisis is the counterirritant action of silver nitrate introduced hypodermically over the vagi in the neck. 5. That acute pneumonia and other forms of acute pulmonary disease are closely affiliated with disorders of the nervous system."

The exposition of Dr. Mays' views is extremely readable, if atavistic in its tendency. We believe, however, that the logic of the author's work is at fault in the essential point that he reasons from a few particulars to universals, a common enough error, but not to be condoned in a work of essayed scientific character. The fact is incontrovertible that certain diseased states of the vagus will cause pulmonary lesions, but after our reading of Dr. Mays' work we cannot alter our conviction that because this relationship is present in certain cases it does not argue for the universal existence of a primary nervous disorder, central or peripheral. Indeed, we believe that the opposite state of affairs is much more likely: that diseased nervous processes frequently occur secondary to bacterial affection. Again, we believe that the reasoning of the work is faulty in that it overlooks the clear distinction between the predisposing and exciting cause. The wide prevalence of tuberculosis makes its association with intercurrent diseases of many varieties most common, and of these we grant the importance of nervous disorder. The effort, however, to prove the nervous affection primary is not in accord with accepted teaching; and neither has the exposition of the theory proven convincing even though it has been cleverly and entertainingly presented. We are prepared to grant that in a certain number of cases in which clinically pulmonary lesions develop, there is excellent reason to believe that the predisposition culminating in the specific infection is due directly to the derangement of the nervous mechanism of respiration; but to our mind it by no means follows that every case of pulmonary disease must have this antecedent cause. In attempting to throw the entire onus of pulmonary pathology upon the nervous system we seem to assume far more than our knowledge of the subject warrants. The complex functions of the vagus are but partially understood and its physiological relations with other organs than the lungs seem to be too little taken into account in Dr. Mays' theory.

He goes to great length to disapprove the contagiousness of tuberculosis, but we believe in all sincerity that many of the cases brought forward to adduce this fact argue strongly for the more generally adopted view. In the author's opinion there is no vital difference between the pneumonias. He

recognizes the general difference between the croupous and the catarrhal varieties, but goes on to say that: "This difference is neither vital nor essentially fundamental; that both are in a great measure the products of the same pathological principle; that clinically one cannot be separated from the other."

Dr. Mays lays great stress upon his interpretation of this word "clinical." It carries to him a practical meaning, a meaning which he has derived from his own observation, and to which he is inclined to attach much more value than to the results of the laboratory study of disease. His views upon pathology are by no means in accord with modern authorities upon this major subject. From a study of his work we conclude that he ascribes to bacteriology but a minor role in the etiology of disease.

Basing his methods of treatment upon his "neurotic" theory (the term is the author's), which he has expounded, Dr. Mays has injected from 4 to 7 minims of a 2½% to even a 5% solution of silver nitrate into the tissues of the neck. "The place which has been selected for its administration is immediately over, or slightly behind, the pulsating carotid artery in the region of the neck, in a line near between the angle of the jaw and the clavicle, and nearer the latter than the former point. Points higher up along the course of the nerve may also be chosen." In the past two years Dr. Mays has employed this treatment in 250 cases with surprisingly good results. Other remedial measures do not seem to have been neglected during this time, and it must appeal to many minds that they are the more reasonable explanation for the betterment of the symptom. Empirically this method does not seem to have wrought any serious damage. Abscesses have occurred about 50 times in some 2,000 injections. Theoretically we hold the measure would appear to be fraught with danger both upon anatomical and physiological grounds. [T.L.C.]

Correspondence.

ALBUMINOUS NUTRITION AND NUTRITIOUS ALBUMEN, BY DR. BERNHEIM.

By A. L. BENEDICT, A.M., M.D.,

of Buffalo, N. Y.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

It has always seemed to me that a published article should be subject to the same full, free, and more or less informal discussion as one that is read before a society. In this spirit I should like to make a few remarks regarding the paper by Dr. Albert Bernheim and that by Dr. A. E. Austin, in your issue of March 9.

It seems doubtful whether Pflüger's dictum concerning the importance of proteid food can be accepted in the clinical sense. Most exhaustive experiments (see Gamgee and other authorities) have shown that muscular exercise does not actually destroy much albumin, either of the muscle itself or of the circulating plasma. Exercise, and in fact, all bodily work involves a comparatively slight wear and tear of tissue and an enormous (relative) combustion of carbohydrates and fats to produce the needed energy. There is, I believe, some evidence to show that brain work requires relatively more proteid than muscle work, comparing equal weights of brain and muscle for strenuous effort for the same time. No one can seriously question the appropriateness of the term "proteid" as indicating that kind of food is absolutely indispensable. On the other hand, the implication of the quotation of Pflüger through Finkler, is misleading as minimizing the importance of carbohydrate food, of which the normal adult organism needs at least four times as much as of proteid. The conditions in Europe undoubtedly are such that the poorer classes eat too little meat, but this con-

dition does not obtain in America, except among recent immigrants, and in some parts of the rural districts. The average American laborer has an abundance of meat, and his diet needs improvement rather in the way of a greater variety of vegetable food, and of having his principal meal in the evening, when it can be served hot and eaten at leisure. Comparisons of dietaries of different classes are also somewhat misleading on account of the greater waste among the rich. Again, it seems remarkable that the waste by failure of non-absorption amounts to 5% for animal proteid, and 35% for vegetable proteid. I do not pretend to be a physiologic chemist, but if this enormous waste exists, why do not our clinical analysis of feces show notable quantities of proteid at all times? Possibly the discrepancy is due to the fact that Dr. Bernheim includes tendon ends, coarse bits of vegetable tissue, etc., yet he seems to refer especially to vegetable flours and meals. These latter ought to furnish feces as rich in proteid as stomach contents, if 35% of albumin is unabsorbed.

Probably Dr. Bernheim can point out the error of our clinical tests, but I believe the clinical fact remains that most of our patients in private practice consume too much meat and too much proteid as compared with carbohydrate. Furthermore, I want to protest against the idea that any artificial nutriment can supplant, except for special purposes and for a limited time, natural food, selected in accordance with a healthy appetite guarded by common sense.

THE FUNCTION AND DISTRIBUTION OF COMBINED HYDROCHLORIC ACID IN PROTEOLYTIC DIGES- TION. BY DR. AUSTIN.

These experiments are interesting and confirm the clinical experience that combined HCl varies widely in amount as compared with proteid, in chyme. They may also serve as a basis for explaining the fact that the common practice of administering pepsin when HCl is indicated, often seems to increase digestive power. I trust that Dr. Austin will continue his experiments, using solutions and time limits more readily comparable with gastric digestion in man. I take it for granted that his percentages of HCl refer to the gaseous acid, though some of his formulæ suggest that the official strong acid—containing about 31% HCl—is meant. This point is of practical importance and should be distinctly stated. The distinction of coagulable from acid albumin is one that can not be made in examinations of stomach-contents, after ordinary test meals, as all albumin is ingested coagulated and any liquefaction must, I suppose, be due primarily to acidification. Was the egg albumin used simply the dried material or was it previously boiled and then dried or estimated as water-free proteid? In my clinical method of quantitating proteolysis in stomach contents (now awaiting publication in the *Jour. Am. Med. Ass'n.*) I have called all proteid precipitated by heat, acid albumin and have successively precipitated albumoses by ammonium sulphate and peptones with phospho-molybdic acid. Dr. Austin's method makes a four-fold division of proteolysis, or a five-fold, if his albumin was first coagulated before being first subjected to digestion. I should be pleased to learn more fully, to what extent he has used the centrifuge in his experiments, so as to give credit for his work so far as it has anticipated mine.

In this discussion I have tried to write much as one would talk extemporaneously, after hearing two interesting and valuable papers, and would be pleased to receive the criticism and explanation, as the readers would have replied in the verbal summing up. Doubtless, many of the apparent differences of opinion are due to the fact that the authors have

taken the standpoint of laboratory research, while mine is entirely that of the clinician, with leisure and apparatus adapted only to clinical investigation of cases.

In conclusion, I should like to suggest that while this particular discussion may have little value, it would add immensely to the interest and usefulness of medical periodicals if printed papers were as freely discussed as those presented verbally to societies; also to urge that all such discussion should be preceded or accompanied by notice to the authors, as a matter of courtesy.

INFUSION OF SALT-SOLUTION IN THE TREATMENT OF PNEUMONIA.—A CRITICISM.

By D. E. KEEFE, M.D.,

of Springfield, Mass.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN the JOURNAL of March 9, 1901, appeared a lucid and timely editorial, giving a synopsis of a paper by Dr. Clement A. Penrose,* of the Johns Hopkins Hospital, advocating the use of saline infusion in conjunction with inhalation of oxygen passed through water containing antiseptics, in the treatment of pneumonia. By way of preface, let me say that I am entirely opposed to the routine use of this solution "in cases of collapse during and after operations, so common in our hospitals," except only when the collapse is preceded by and is consequent on blood-loss. Oxygen, with or without antiseptics, has a certain value in a number of cases of pneumonia. But I am certain that very little can be adduced in favor of saline infusion in pneumonia, but, on the contrary, much in opposition. Indeed, its use before the stage of gray hepatization is wholly indefensible. Busy physicians are, I fear, too apt to take *post hoc* for *propter hoc* in such matters. For example, in syncope and collapse, while the regular physician prescribes diffusive stimulants, his confrere of the Hahnemannian persuasion employs aconite. In both cases, and with medicines acting in diametrically opposite directions, the heart responds and the patient is resuscitated. The physicians of both schools are firmly convinced that the reaction is proof positive of the correctness of their medication, each believing he has saved a life. But they have entirely overlooked the fact that, in a third case, where no medicine was given, a like recovery took place. The difficulty is that they did not calculate on that great power in medicine of which we hear so much, the *vis medicatrix naturae*. They should remember that the heart is prone to make just such responses, and that, too, without medication and where least expected.

Both the saline infusion and the stimulant plan of treatment, now in vogue, are unphysiological as applied to pneumonia. They promote activity, and seek to send more blood to the affected in common with all other parts, whereas correct physiological teaching demands rest and abstraction of blood. They fail in pneumonia because in the inflamed lung there is almost complete stasis, by reason of the exudate outside and the clotting within the vessels. No matter what the degree of stimulation, this impediment cannot be overcome, and the blood cannot be forced through. In consequence of this the treatment accomplishes nothing, and, indeed, may be carried so far that the heart, already overacting, becomes exhausted and strikes work. Moreover, the sending of more blood to the nonpneumonic lung, which is, under such circumstances, always congested, tends to pro-

duce edema, as very properly pointed out in your editorial, and also pneumonia. Until an equivalent for the added saline infusion is eliminated, by the skin and kidneys, and although the heart may not be stimulated to the extent obtaining when medicinal stimulants are used, the great addition to the circulating fluid and consequent increase in pressure sends a greater quantity of blood in every direction, and especially toward the lungs. Thus is stimulation by medication and by saline infusion, in so far as they affect the circulation, tantamount to the same thing, the only difference being that the infusion places an additional burden upon the heart, and one of which it must be relieved. Experiment and observation have established as a fact that the heart promptly responds to irritants or stimuli whether externally or internally applied. Thus, dashing cold water on the face is followed by a gasp, then increase in the depth and number of respirations and increased heart action. So, also, a cold bath, physical exercise, the ingestion of a considerable quantity of food or drink, whether introduced through the alimentary canal, the skin, or directly into a bloodvessel, elicits a like response. The degree of reaction varies with temperature, and many other circumstances. As a matter of course, the same phenomenon follows the ingestion of saline solution, but is not inherent to it any more than to a like quantity of water or milk. If it is justifiable to inject any fluid in this manner during an attack of pneumonia, that fluid is antipneumotoxin serum. Then we would at least get the specific effect, and if largely diluted, all the good effects claimed for saline infusion. Dr. Penrose prefers infusion to transfusion, but the difference is rather one of degree than of kind. The more rapid the ingestion, the larger the quantity thrown into the circulation within a given time, the greater reaction and the greater the danger. So that, while infusion is safer, it is also less prompt and, so far as inducing reaction, less efficient.

With regard to "diluting the toxins and promoting their elimination," I should say that whatever may be thought of eliminating them through the skin, and I for one am sceptical, as to the kidneys I say nothing, but in the lungs, where they are mostly situated and where most of the damage is wrought, they are inaccessible to the saline solution by reason of the stasis, clotting exudate, etc., as before explained. Suppose that, for the sake of argument, we admit that the blood and saline solution could circulate freely through the pneumonic lung, by just so much as it diluted the blood and toxins, would it also dilute the hemoglobin, and, hence, lessen the ability of the blood to carry oxygen at just the time it is most needed. I am aware of the small quantity of free oxygen found in the blood, but it is of no consequence for purposes of oxygenating the tissues. Regarding the cardiac second sound and its accentuation being an index for bloodletting; it is always too accentuated in a pneumonia of any extent by reason of the pulmonary artery's inability to empty itself, hence this sign has no value.

Considering the matter, then, from every point of view, we cannot agree that "saline infusion is a decided advance in treatment." Neither are we familiar with anything in the chemistry of oxygen that would lead us to expect any assistance from saline infusion in promoting its absorption or utility. Had the doctor proposed to first abstract a quantity of blood equal to the saline solution to be infused, then he could reasonably claim he was getting rid of so much at least of the toxins as the withdrawn blood contained, just as we do in uremia, and of diluting those remaining in the blood. At least he could not be held accountable for adding to the

* By the kindness of Dr. Penrose I have read his original paper.

labor of a heart already working at a disadvantage and at the point of exhaustion.

In conclusion, I contend it is never safe or justifiable to suddenly make any considerable addition to the circulatory fluids at the acme of an acute disease like pneumonia. (a) The added fluid cannot circulate through the affected lung to any extent; (b) it tends to cause edema and pneumonia in the unaffected lung; (c) it dilutes the hemoglobin, and so is an impediment at a moment when this is most needed; (d) it places an additional burden on the heart (its propulsion and elimination); and, finally, it tends to paralyze the capillaries, destroy vessel tonus, and overwhelm the heart, while all the good it accomplishes may be effected by other agents not involving like objections and dangers.

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA.

British Society of Public Analysts.—Dr. Henry Leffmann of Philadelphia has been elected a vice president of the British Society of Public Analysts.

Charity Hospital.—In the dispensary clinics of the Charity Hospital, 1731 Vine street, there were treated last month 322 medical cases, 53 surgical, and 162 of women and children, and 775 prescriptions were dispensed.

West Philadelphia Hospital for Women.—The report of the West Philadelphia Hospital for Women for February shows that on February 1 there were 20 patients in the hospital; received during the month, 17; registered in dispensary, 60; registered in out-practice visits, 246; operations in hospital, 8; operations in out-practice, 6.

Death of Dr. Edward Clarence Fraser.—Dr. Edward Clarence Fraser, who was at one time attached to the staffs of the Polyclinic and Jefferson Hospitals, died at his home, 646 North Eighth street, Thursday, of heart failure. Dr. Fraser was 61 years of age, and was a graduate of the University of Maryland and Jefferson Medical College. He also took a post-graduate course in the New York Medical School and Hospital.

Surgical Treatment of Cirrhosis of the Liver.—Cases continue to multiply of the so-called operation of epiploxy. This is an operation for establishing a collateral circulation, by which the abdominal dropsy in cirrhosis of the liver is absorbed. Of course, it is merely a palliative operation, and does not, and cannot, influence the pathological process in the liver itself. It consists essentially in stitching the omentum to a denuded, parietal surface of the peritoneum. Dr. Frazier, of Philadelphia, was one of the early operators, and published a statistical paper, based on all recorded cases up to December, 1900. Recently, Dr. Jelks, of Hot Springs, Ark., has reported a case with satisfactory results (*Medical Record*, March 23). In the PHILADELPHIA MEDICAL JOURNAL for January 26, Dr. John B. Roberts reported 2 cases, in a paper entitled "Epiploxy in Cirrhosis of the Liver." These cases are inadvertently omitted by Dr. Jelks in his references to reported cases.

Neurological Society.—A stated meeting of the society was held March 25, the president, Dr. JAMES TYSON, in the chair. Dr. F. X. DERGUM exhibited a man of 37, who has a combined surgical and nervous lesion. The upper part of the left arm is more than 2 inches shorter than the right, supposedly due to an early epiphysitis of the upper end of the humerus and consequent lack of development. There is also pain in that shoulder which radiates to the neck and at times involves the eyes. The condition is apparently one of hysterical joint superimposed upon the old lesion. This is the third case of epiphysitis seen by Dr. Dergum.

Dr. A. R. MOULTON reported **A case of fracture of a thin skull and hemorrhage into the brain.** The subject was a patient at the Pennsylvania Hospital for the

Insane who was found dead in his room. The skull was fractured, apparently by a fall from the bed, and was found to be very thin, from .02 to .04 inches, and exceedingly brittle.

Dr. ALFRED GORDON read a paper entitled **The role of infection and intoxication in diseases of the spinal cord.** The frequency with which microorganisms are found in connection with various lesions of the cord was stated. Serumtherapy will probably play an important part in future treatment.

Dr. CHAS. S. POTTS exhibited a case of **multiple sclerosis with unilateral ascending progressive paralysis.** An interesting point in this case of multiple sclerosis of unusual type was the history of attacks of rheumatism before and during the presence of the disease.

Dr. WILLIAM C. PICKETT read a paper on the **Scapulo-humeral reflex of Von Bechterew.** The paper was a report of the study of this sign in 122 cases at the Philadelphia Hospital. The reflex was entirely absent in 40 cases. The frequency of its occurrence in various lesions of the nervous system was detailed. Adduction and external rotation of the arm were found to be less constant than abduction with slight flexion of the elbow. The presence of the reflex is considered to be significant, while its absence is of uncertain value.

Dr. MOSES BEHREND (by invitation) read a paper on **The biceps-tendon jerk in locomotor ataxia.** The results of the study of 29 cases of tabes were given. The biceps jerk was present in 9 cases, the triceps jerk on both sides in 2 cases, and on one side in 2 cases. When the biceps tendon jerk is absent there was generally marked ataxia in the arms. The intensity of shooting pains seemed to have no relation to the degree of ataxia present. The intensity of the symptoms were not found to be dependent on the duration of the case.

Vital Statistics of Philadelphia for the week ended March 23, 1901:

Total mortality	CASES.	DEATHS.
Inflammation of appendix 3, brain 15, bronchi 8, kidneys 27, liver 3, lungs 80, pericardium 1, peritoneum 2, pleura 5, stomach and bowels 14		164
Inanition 12, marasmus 13, debility 6		31
Tuberculosis of lungs		70
Apoplexy 15, paralysis 11		26
Heart—disease of 31, fatty degeneration of 2, neuralgia of 2		35
Uremia 8, diabetes 6, Bright's disease 4		18
Carcinoma of bladder 1, breast 1, stomach 3, uterus 2, face 2, rectum 1, tongue 1		11
Convulsions		14
Diphtheria	73	15
Brain—congestion of 1, disease of 4, hemorrhage from, softening of 4		10
Typhoid fever	30	3
Old age		20
Cyanosis		1
Scarlet fever	85	5
Influenza 12, abscess of neck 1, aneurysm of aorta 1, alcoholism 1, asthma 3, atheroma 1, burns and scalds 1, casualties 4, congestion of lungs 4, cirrhosis of liver 3, membranous croup 2, diarrhea 2, dropsy 1, dysentery 2, erysipelas 1, hernia 1, obstruction of bowels 3, edema of lungs 1, rheumatism 5, sarcoma of neck 2, arteriosclerosis 1, septicemia 1, suicide 2, teething 1, abdominal tumor 1, of liver 1, unknown coroner case 1, whooping-cough 4, dropsy of brain 1		64

College of Physicians—Section on Gynecology.—A stated meeting of the Section was held March 21, the President, Dr. JOHN C. DaCOSTA, in the chair. Dr. W. REYNOLDS WILSON read the report of a **Cesarean section in a case of obliquely contracted pelvis.** The case belonged to that class in which the diagnosis may be overlooked when only the pelvic measurements are considered, the distance between the spines and between the crests being 28 cm. There was a history of progressive deformity, 2 of the 4 previous children having been delivered by decapitation. A previous lumbar abscess and the progressive deformity suggested tuberculosis, but this condition was finally excluded, the history and condition together pointing to an original rachitic deformity. Dr. E. P. DAVIS said that there were occasional cases in which the causes of oblique pelvis were

injuries during adolescence. Two cases were cited, one due to disease of the knee-joint with final ankylosis, the other caused by a temporary injury to the lower extremity. Cesarean section is the choice of operation in these cases, and in instances of a second confinement it is hardly wise to induce labor even at the end of 8 months.

DR. BARTON COOKE HIRST gave clinical memoranda of several cases: 1. **Partial hysterectomy for necrosis of the uterus due to streptococcus infection.** Total hysterectomy was formerly performed in cases where a portion of the uterus was found to be softened and necrotic. In 2 recent cases recovery is believed to have been due to the removal of only a part of the uterus. The method is suggested as being more quickly and easily done than a total hysterectomy and as one causing less shock to the patient. 2. **The removal of ovarian cysts under conditions seemingly unfavorable.** The case reported was that of the removal of an intraligamentary cyst from a woman over 50 years of age who had an aneurysm of the arch of the aorta. Recovery was uneventful. To prevent infection from the large raw surface left, a puncture through the vaginal vault was made for drainage and peritoneum sutured over the area in such a way as to exclude it from the abdominal cavity. 3. **The treatment of lacerated cervixes directly after labor.** Dr. Hirst's experience is that primary operations directly after labor are not satisfactory. In 4 days involution is so far advanced that sutures will hold, but it is better on account of the lochial discharge to wait 2 weeks. Laceration of the cervix is often complicated by laceration of the perineum. In such cases when repair of the cervix has been decided upon the perineum is allowed to go for 2 weeks and both operations done at one sitting. DR. E. P. DAVIS stated that his experience with immediate closure of the wounded cervix had not been distinctly unsatisfactory. Hemorrhage sometimes demands the insertion of sutures and these often give good results. The danger of infection may be increased by waiting. If the operation is postponed for 2 weeks, lactation may be interfered with in patients of a certain temperament. DR. DAVIS asked if choice of suture material had any influence in causing poor results in early operations. DR. J. B. DEEVER, while not a believer in intraspinal cocaine-anesthesia, stated that the woman with the aneurysm would seem to have been a proper case if it should be used at all. He has tried it in a case of suppression of urine due to a stone in the pelvis of the kidney, the other kidney having previously been removed. The trial resulted in failure, and chloroform was successfully used. Dr. Hirst stated that he used silkwormgut sutures in repairing the cervix. In the case referred to, spinal anesthesia had been strongly urged by the physician of the patient, but owing to the discouraging nature of inquiry regarding its results Dr. Hirst decided against it. He is confident that the woman did better under ether and prefers that anesthetic as a routine.

DR. R. P. McREYNOLDS reported a case of **Ruptured interstitial ectopic gestation.** The symptoms of ectopic gestation were typical. The woman died 12 hours after operation in which the portion of the uterus involved was removed by means of a V-shaped incision. Intravenous infusion of saline solution was given after operation. From the results in this and other cases Dr. McReynolds believes that intravenous infusion is a somewhat dangerous proceeding in patients having such general condition. DR. HIRST said that interstitial pregnancy must be a rare condition since in his 42 cases of ectopic gestation only 1 was anything like interstitial in location. He prefers submammary hypodermoclysis of salt solution. If a vessel were used he would prefer the radial artery instead of a vein, as the solution would not go so directly to the heart, and the danger of air embolism would not be so great. DR. E. P. DAVIS stated that he had used intravenous infusion of saline solution in several cases and no accident could be traced directly to it. DR. J. B. SHORER considers submammary injection satisfactory and less dangerous than intravenous. DR. J. B. DEEVER recommends intravenous infusion and considers it one of the greatest boons of modern surgery. It finds its best application in cases of hemorrhage, but is of value in general sepsis. In some cases the residents at the German hospital do not sew up the wound in the arm, but use it for a second infusion. Dr. Deever believes there is more risk of infection from the

submammary method and would not advise the arterial route. DR. JOHN C. DA COSTA has found the intravenous method satisfactory in every case in which he has used it. He has seen abscesses result from submammary injection and does not like that method. DR. McREYNOLDS stated that intravenous infusion of saline solution is of value in recent injuries as crushes, etc., but where bleeding has kept up for a period of days, as in the case reported, the heart accustoms itself to the condition present and infusion may do damage.

NEW JERSEY.

Legislation for Undertakers.—An ordinance, drawn similar to the one operative in Philadelphia, placing restrictions on persons engaged in the undertaking business, was under consideration by the Camden Board of Health. It provides that all persons now engaged in the business shall pay a license fee, to be fixed later, and that hereafter all persons desiring to enter the business must undergo an examination as to their fitness. The ordinance also prohibits non-resident undertakers from conducting a city burial unless they have a license, and instructs the nuisance inspector to inspect all undertaking establishments.

NEW YORK.

Elected Professor of Internal Medicine.—Dr. Heinrich Stern has been elected professor of internal medicine in the New York School of Medicine.

Dr. S. A. Knopf Receives First Prize.—The Department of State has been informed that the Berlin tuberculosis congress has awarded the first prize for papers on the subject of tuberculosis to Dr. S. A. Knopf, of New York, and has arranged for the publication and distribution of his paper with a view to using the proceeds in the establishment of sanitariums for the treatment of that disease.

Change of Date of Annual Meeting.—Owing to an oversight the dates selected for the annual meeting of the American Laryngological, Rhinological and Otological Society are the same as those of the American Climatological Society. The American Climatological Society is to meet in Buffalo, and owing to the crowded condition of Buffalo during the Exposition it would be difficult for them to change their date. The annual meeting will be held at the N. Y. Academy of Medicine in the city of New York on May 23, 24 and 25, 1901.

New York Obstetrical Society.—Stated meeting held March 12, 1901. The president, DR. H. J. BOLDT, in the chair.

DR. BACHE EMMET presented a specimen of sarcoma of the ovary. The tumor was removed 2 weeks ago from a patient having the following history: aged 49, multipara, married, menopause 6 years ago. One brother had cancer in the abdomen, one sister had a tumor of the lower abdomen. Within the last 3 or 4 years the mass has grown until now it is the size of a football. The mass was attached by its own ligament, and had a few thread-like adhesions. There was no derangement of the general health, and the woman has not suffered. The tumor proved to be of the round-celled variety. As the growth was essentially local, and the attachment so small, he felt like encouraging the patient to feel no apprehension. He was aware, however, of the fact that there might be a return of the malignancy in a few years.

DR. VINEBERG could recall 2 cases of spindle-celled sarcoma, operated upon by him, one 2, the other 3 years ago. Both patients are in good health today. During the past summer he had operated upon a patient, the tumor proving to be a round-celled sarcoma. It is more than 9 months since operation, and as yet there has been no recurrence. DR. BOLDT said that one of the cases he had reported had died shortly after operation, and that the second had a recurrence in the abdominal wall which he had operated upon a year later. DR. WALDO said that the last patient referred to by Dr. Boldt was alive and well 2 years after, without recurrence. He had operated upon a case — years ago, and during the past year he had opened the patient's abdomen again, finding the growth too extensive to remove.

DR. GRANDIN presented a specimen of **ectopic gestation**, removed from a patient 23 years old, who had had 2 children,

the last 2 years ago. She menstruated every 4 weeks, the flow lasting 7 to 10 days. She menstruated last on February 15, the flow lasting 12 days. On March 1, she again began to flow and continued. There were no colicky pains or data to suggest pregnancy. There was a mass behind and to the left of the uterus. Under ether the uterus was curetted. There was no enlargement. Postvaginal section gave exit to blood and clots. Abdominal section was made for removal of left ruptured tube. There was almost a quart of clots and blood in the peritoneal cavity.

DR. GEORGE G. WARD, JR., read the paper of the evening. His subject was **The Prevention of Postoperative adhesions of the peritoneum.** The author remarked that one who comes in contact with patients after they have been subjected to peritoneal operations must surely be impressed with the fact that we have still much to learn before we can invade the peritoneal cavity without leaving that delicate membrane in a crippled condition; in a large per cent of cases, as is evidenced by continued pain, constipation, and in some cases such bands of adhesion that subsequent operation is necessary. He called attention to the fact that more is necessary for the welfare of the patient than simply to be able to open the abdomen, remove an organ or growth, and suture the wound without loss of life from hemorrhage or sepsis.

A summary of the means of prevention he advocates is as follows:

1. The attainment of asepsis as perfect as is possible by the rigid adherence to the most modern methods of securing surgical cleanliness.
2. The avoidance of raw surfaces and pedicle stumps by covering them with peritoneum, or grafts of omentum, and the abandonment of the ligature en masse.
3. Protection from dry air contact by the employment of moist asepsis instead of dry asepsis, and keeping the exposed parts covered whenever possible.
4. The time element—rapidity of operating by technical skill, thorough preparation, and trained assistants.
5. Keeping up the heat of the peritoneal cavity by frequent renewal of the hot salt-solution (115° F.), and by protection of the exposed parts.
6. Avoidance of excessive manipulations of the intestines by technical skill, proper anteoperative preparation of the bowels and posture to prevent pseudoileus.
7. Replacement of the loops of intestine and omentum by filling the abdominal cavity with hot salt-solution before closing, and thus floating them that they may more readily adjust themselves in their proper relations.
8. Free motion of the patient after the operation to be encouraged instead of prohibited.
9. Early use of the high enema during the first 12 hours in conjunction with cathartics, and on failure the prompt use of oxygen in the exaggerated Trendelenburg posture.

Conclusions.—My study of adhesion formation and the best means of their prevention leads me to the following conclusions: 1. That peritoneal adhesions after operation result from several causes. 2. That therefore we can not depend upon any one preventive method, but, recognizing their multiple etiology, we must employ all the details of operative technic that are necessary to offset the various causes. 3. That this necessitates a technical skill that can only be attained by a long apprenticeship and a thorough training in abdominal surgery. In closing, the speaker said that in his opinion, the surgeon who most conscientiously looks after all the details will have the fewest postoperative cases of adhesions with their unfortunate sequelae.

NEW ENGLAND.

American Laryngological Association.—The Twenty-third Annual Congress of the association will be held at New Haven, Conn., Monday, Tuesday and Wednesday, May 27–29, 1901. The president of the Congress is Dr. Henry L. Swain, of New Haven.

CHICAGO AND WESTERN STATES.

Convicts Vaccinated.—The 1,000 convicts in the Illinois penitentiary at Joliet, are being vaccinated, and the utmost care is being taken to prevent smallpox from breaking out among the prisoners.

Minnesota Senate Passes Marriage Bill.—The State Senate passed Senator Chilton's bill prohibiting the

marriage of insane, epileptic and idiotic persons, and requiring a medical certificate of all applicants for marriage licenses. Amendments were adopted making the physician's certificate not quite so sweeping and to permit marriage of any feeble-minded person over 45, the bill originally having extended such permission only to women.

Succus Capricornus.—All the way from California comes the news that there is a "regular" doctor out there somewhere who is exploiting a brand-new lymph treatment. He has even bought the exclusive right to this alleged therapy. The lymph, we are credibly told, is "straight Rocky Mountain Goat Juice." This doctor is soliciting and practising business in the treatment of chronic and wasting diseases, especially tuberculosis, locomotor ataxia and premature senility, by the use of this wonderful lymph, which a local observer calls a "hircine balm of Gilead." This juice is elaborated with such care and such unique skill as to preserve, with ever increasing potency, the original "cell life." It causes marvelous changes for the better to take place in the structure and chemical composition of bones previously diseased within two months and a half after beginning a twice a day injection. This was demonstrated in the laboratory and under the microscope upon an aged dog that had been rejuvenated capricornically. And the impression is somehow created that so strenuous and exuberant was the physical vigor and vital tenacity of that canine compromise twixt Job and Methuselah, transmogrified by the Succus Capricornus, that it was only with the extremest difficulty that the creature was killed sufficiently dead to make it safe for chemist and microscopist to trifle with his remains. From all this it appears that serumtherapy is well advanced on the Pacific coast.

Chicago Pathological Society.—Meeting held March 11, 1901, Dr. L. Hekton, president.

DR. MAXIMILIAN HERZOG read a paper on **Primitive splenomegaly, or anemia splenica.** The paper was based upon a study of the literature of the subject, and upon two cases in which Dr. M. L. Harris had performed splenectomy. Particularly one of the two cases, both of which got well after the removal of the spleen, had been studied carefully since; two years had elapsed since the operation. Before the operation there had been present in this case a marked diminution of the erythrocytes, a low color index, and an absolute and relative reduction in the number of the leukocytes. The blood had improved very much since splenectomy, and there had developed a marked eosinophilia. An examination of the spleens removed showed a marked endothelial proliferation with enlargement of the blood lymph-spaces (pulp spaces). Herzog stated that he had in vain sought for many destroyed blood-corpuscles inside of lymphendothelia, a picture as it is, for instance, found in typhoid fever. Considering the fact that the blood-condition had always improved in all cases of splenomegaly in which splenectomy had been performed, provided the patient did not die from the operation, it appeared conclusive that the changes in the spleen must be looked upon as the primary factor in the disease. We therefore must look to the pathological changes in the spleen, as the cause of the blood-destruction. From an examination of the two cases as well as from a study of the literature it appears that no evidence can be found that lymphatic endothelia destroy the blood by directly taking up blood-corpuscles. Herzog, therefore, advances the theory that lymphatic endothelia of the spleen and of lymph glands secrete an erytholytic ferment and in this manner destroy old and worthless blood-corpuscles. We have in splenomegaly an enormous endothelial proliferation and probably in consequence an enormously increased production of the erytholytic ferment, which when present in such a large amount destroys many healthy blood-corpuscles. If the spleen is removed the source of the increased production of the erytholytic enzyme is removed and the blood improves rapidly and permanently. In the discussion Dr. W. A. EVANS referred to the case of Dr. Ferguson in which there occurred petechial spots in the skin and where the spleen became smaller before death. He spoke of a case reported by Dr. Dalton before the London Clinical Society, which was clinically one of splenic anemia, but at autopsy the enlargement of the spleen was discovered to depend upon passive

congestion, due to constriction by an anomalous colon. DR. LEO LOEB declined to accept the theory of an enzyme which destroys the red blood-cells in the spleen. DR. E. H. OCHSNER referred to a case which clinically was splenic anemia, and which improved for a time after the spleen was removed, but subsequently died. There were a few small peritracheal glands found at autopsy which were tuberculous. A possible infection in such cases must always be considered. DR. B. W. SIPPY spoke of the similarity of these cases to the ordinary lymphatic pseudoleukemia as regards blood changes, general asthenia, etc., a similar enlargement of the spleen also being observed. In many cases of splenic anemia there is enlargement of the lymph glands, although it may be slight. In all cases the bone marrow has been converted into a fetal condition, like that found in many cases of pseudoleukemia lymphatics. He objects to the term splenic anemia, and considers the one splenic pseudoleukemia to be the proper one. He believes the primary cause cannot be positively located in the enlargement of the spleen. In the case described by himself, the fibrous changes were much more marked than in Dr. Herzog's. This he thinks may depend upon the longer duration of the disease. DR. P. KYES said that in the specimens of Dr. Herzog, the proliferation involves all the structures of the spleen, and such a condition cannot be due to a primary proliferation of any one element, as the endothelium. DR. T. R. CROWDER presented sections of an amyloid spleen with unusually distinct endothelial linings in the vascular spaces. DR. HERZOG in closing said that he did not claim that there was proliferation of the endothelium alone, but that the increase in the endothelium was enormous, so much so that the condition had been mistaken for an endothelioma. Dalton's case had not been considered as it was too indefinite. One reason for separating these cases from lymphatic pseudoleukemia is because they are curable by operation.

DR. THEO. TIEKEN exhibited a specimen of **pancreas annulare**, with resulting constriction of the duodenum so that a large fusiform sacculum of the latter had formed.

DR. H. M. RICKETTS presented specimens of **experimental general blastomycosis in the dog** produced by an intravenous inoculation of an organism obtained from a case of blastomycosis of the human skin.

The Chicago Hospital-School for Nervous and Delicate Children.—This school was originally incorporated in 1899 as the Chicago Physiological School; it has now 16 children under treatment and care. The hospital-school is located on Drexel avenue, Chicago, near Drexel square. Owing to the capacity being overtaxed a movement is now on foot to arrange for more commodious quarters.

The incorporators of the school were Dr. W. R. Harper, president of the University of Chicago; Prof. George H. Mead, associate professor in philosophy of the University of Chicago, and Miss Mary Campbell, founder of the school.

The executive committee consists of Prof. George H. Mead, president; Dr. Henry H. Donaldson, vice-president; and Miss Mary Campbell, secretary and treasurer.

The Board of Trustees also include Mr. A. C. Bartlett, Dr. Nicholas Senn, Dr. John Dewey, head of the department of philosophy and psychology, Mrs. A. C. McClurg, Mrs. C. R. Crane, and Mrs. J. Young Scammon.

The institution was established for the care and treatment of children incapacitated from receiving regular instruction owing to slight physical defects, such as stammering, stuttering, nervous troubles, minor ear and eye trouble, for children obliged to be under medical care and yet capable of receiving a certain amount of educational work, and for those needing corrective work in speech, etc. Children from 4 to 15 years are accepted for treatment.

The school has three regular nurses, a faculty of eight teachers, and a regular consulting staff of physicians, among whom are Dr. Frank Billings, Dr. Archibald Church, Dr. Hugh T. Patrick, Dr. D. R. Brower, Dr. Nicholas Senn, Dr. N. B. Delamater, Dr. Frank Allport, Dr. Eugene S. Talbot, Dr. John Ridlon, Dr. Llewellyn Barker, and others.

The School has recently been affiliated with Rush Medical College and the educational work is supervised by the Department of Neurology and Philosophy of the University of Chicago, the University advisor being Dr. H. H. Donaldson.

The Hospital-School is to be used as a laboratory for the study of mental phenomena of subnormal children.

SOUTHERN STATES.

New Morgue.—Plans for the erection of a new morgue at Washington have been submitted to the Commissioners. In addition to the mortuary, there will be a room for postmortem examinations and a capacious room for laboratory purposes.

Health Officers' Association Organized.—At a meeting of State, county and city health officers held on March 21, the organization of the Health Officers' Association of Texas was effected. The following officers were elected: President, Dr. J. B. Massie, of Houston; vice-president, Dr. I. J. Jones, of Austin; secretary and treasurer, Dr. J. M. McCutcheon, of Temple.

Defence of Dr. Loeb.—In the Corporation Court of Newport News, the case of Louis Loeb, the well-known physician, will be tried. Dr. Loeb was indicted several months ago on the charge of practising medicine without a license or a certificate from the State Board of Medical Examiners. It is said that the doctor will admit everything charged by the Commonwealth, but will contend that the law is unconstitutional.

CANADA.

From Our Special Correspondent.

McGill University is the fortunate possessor of many good friends—friends in deed and action as well as in name. Sir William Macdonald has again loosened his purse-strings and McGill is the richer by \$150,000. Of this sum \$75,000 will be taken to endow the chair of chemistry, \$32,500 for the chair of botany, and \$12,500 will be added to the chair of physics. Prior to this donation, Sir William had already given the University \$2,500,000. Another gift is also announced, Miss Jessie Dow having given \$60,000 for a chair of political economy. Nor, indeed, is the Medical Faculty forgotten. Another large addition will be made to the medical building this summer. It will be four stories in height, and be provided with a large number of lecture rooms, museums, and chemical laboratories. The cost of this proposed addition will be borne by Lady Strathcona and the Hon. Mrs. Howard.

The Extent of Cancer in Ontario.—The report of the provincial board of health shows that from the years 1886 to 1899 inclusive there were deaths from this cause as follows: 440, 614, 635, 714, 685, 579, 676, 678, 621, 620, 731, 927, 975, and 1,041 in 1899. These figures indicate that those diseases included under the name of cancer are on the increase in the province of Ontario. Prior to 1896 it will be noticed that these returns show no notable increase, but since that time there has been a remarkable increase. Probably this may be due to the fact that many deaths formerly included under "tumors," are now set down to cancer, through more description in death returns. Another cause may be set down to the great increase in the hospital population of the province, which in 1885 numbered 5,000, now amounts to 20,000; and the increase in hospital accommodation bringing with it better accuracy in diagnosis would also tend to augment the statistics of cancer.

The bill for the treatment of inebriates in Ontario has apparently very little chance of going through the Legislature this session, although it was prepared in the early part of last session, at which time it was fully expected that the Government would introduce it. Notwithstanding that the bill has been approved by the Premier, by the inspectors of prisons, and by the Warden of the Central Prison, himself a medical man, as well as by many of the members of the Government, the Government continues to dally with this legislation. The Ontario Medical Association and the Toronto Medical Societies have sent deputations to interview the Government on the matter time and again, and although the Government has been great in promises, it has also been very small in action. In this matter the Government is woefully dilatory; but an election is near at hand, and a long-suffering profession and public may be expected to take advantage of the opportunity for getting even on many an old score through the triumph at the polls of a progressive Opposition.

A Medical Council for the whole Dominion, the Bill concerning which has recently been introduced into the Dominion Parliament by Dr. T. G. Roddick, M.P., will soon be consummated, providing the present Bill goes through the House. It provides for a central medical council, upon which will be three representatives from each of the eight provinces in the Dominion; and the homeopaths will also be given three representatives, appointed by that body throughout the country. The composition of this council will be the President of each Medical Council of every province, ex-officio, one member elected from the Medical Council of each province, and one from each province elected by the Governor-General in Council. It provides also for examinations and a course of study of 5 years as already existing in the province of Ontario. During the course of his address to the House, Dr. Roddick gave some interesting details of the history of medical education in Canada, and also concerning the medical population of each province. Prince Edward Island has 90 medical practitioners; Nova Scotia, 476; New Brunswick, 243; Quebec, 1,400; Ontario, 2,500; Manitoba, 344; North West Territories, 95, and British Columbia, 214.

The Annual Report of the Quebec Board of Health gives some interesting information in connection with the health of that province. Notably is the law in regard to cases of tuberculosis of the lungs in advance of that of any of the other provinces. There, every householder in whose household a death occurs from pulmonary consumption must notify the secretary of the local board of health of such death within 48 hours of its occurrence. Upon such notification being given the municipality is bound to cause the disinfection of the apartments which may have been contaminated by the patient. The rate of death in different Canadian cities from tuberculosis is set down as follows: Quebec City, 1.99 in 1,000; Ottawa, 3.12; Montreal, 2.87; Kingston, 2.17; Toronto, 2.41, and London, 2.67. It would thus appear that Quebec City was the most free of the dread disease and Ottawa the most infected. Quebec can point with unalloyed joy and pride to her birth-rate. In the year 1898 the birth rate was 35.70, which, compared with that of Ontario, is greatly in excess of the latter, which was 20.4 for the same year. In 1899 the birth-rate was 33.46, which meant a decrease of 3,535. Still with this decrease, Quebec can be consoled, as she has the highest birth-rate of any country except Germany.

Government aid for Toronto University is promised in a measure laid before the Ontario Legislature last week by the Hon. Mr. Harcourt, the Minister of Education for the Province. The particulars of the bill, however, do not meet the entire approval of the friends of the provincial university. They had expected a great deal more than will be given. Although the university has gone behind to the extent of \$30,000 or \$40,000 during the past three years, they are now only promised \$20,000, which must be devoted exclusively to the chemical and physical branches. The friends of the university had fully expected \$50,000 at the very least. An item of great importance in the bill takes the control of the institution out of the hands of the Government and invests it in a board of trustees. This is a sort of sop to the moneyed men of Toronto, who heretofore would not indulge in donations in aid of the work of the university so long as it was under the direct control of the Ontario Government. Provisions are also made in regard to the proposed federation of Trinity and Toronto Universities, and incidentally the medical faculties in affiliation therewith. This latter, however, now seems to be off the boards for some time, as Trinity Medical College, through Dean Geikie, has given out that they will not amalgamate on the lines proposed, which in the main amounted to the fact that all the professors, lecturers, and demonstrators were to be kept on for two years by the united institution, and then a new faculty formed therefrom. Amalgamation of Trinity and Toronto may then be said to be as far off as ever it was. The Government has promised to erect during the next two years a new building for the science departments at a cost of \$200,000, but this is taken by many of the friends of the university as a mere election dodge.

MISCELLANY.

Obituary.—DR. WRENN, Bridgeport, Conn., on March 23.—DR. EDWARD S. FAWCETT, at Alexandria, Va., on March 21.—DR. P. A. HOLOHAN, at Springfield, Mass., on March 11.—DR. OLIVER P. WOLCOTT, at Milwaukee, Wis., on March 16.—DR. GEORGE M. FISHER, at Denton, Md., on March 20.—DR. H. G. HOLLENBECK, at Willow Springs, Mo., on March 22.—DR. ALFRED R. GREEN, at Greely, Col., on March 22, aged 79 years.—DR. JOSEPH TELLYESNECKY, at Chicago, Ill., on March 14, aged 40 years.—DR. J. S. SCOFIELD, at Hillsboro, Tex., on March 23, aged 75 years.—DR. RALPH J. HESS, at North Brother Island, near New York, on March 24, aged 27 years.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended March 23, 1901:

General Wood's Case Not the Only One.—Our recent reference to General, or Doctor, Leonard Wood's promotion in the U. S. Army has aroused the interest of many persons. We have received information about the following army officers, which is worth knowing:

Brigadier-General Ainsworth, at present chief of the Record and Pension Division, War Department, Washington, D. C., was promoted to that place from the position of major and surgeon, U. S. Army, as a result of bringing the affairs of that division, while temporarily acting in charge, into a most admirable condition of efficiency. He was first promoted to a colonelcy, and was subsequently raised, in 1898, to the rank of brigadier-general as a result of his admirable administration of the affairs of his bureau.

Brigadier-General Myer, late Chief Signal Officer, U. S. Army, invented and perfected the Myer code of military signalling, now used in all the armies of the world, while serving as an assistant surgeon, U. S. Army. For his work in connection with military signalling he was made a brigadier-general and appointed the chief of the Signal Corps.

The case of Major-General Crawford was given in the last number of the JOURNAL. It is a curious fact, illustrative of the difficulty of obtaining accurate information on these subjects, that from one source we learn that Gen. Crawford was killed in action during the Civil War, while from another we learn that he was retired with honor in 1873.

Surgeon-General Lawson, who was chief of the Medical Department of the Army prior to the Civil War, had served with much credit during the Seminole War in Florida as lieutenant-colonel of an infantry regiment.

The moral of these promotions, together with that of General Wood, seems to be that the Medical Department of the Army is fully as much a military as a professional organization, that a large proportion of its members possess military qualifications of a high order, and that a medical training and executive ability are far from incompatible.

Further, it would appear that the line, when an unusually good man is needed to fill a position of emergency, have sometimes to go to the Medical Department of the Army to get him.

EDWARD L. WHENSON.

Capt. Asst. Surg. U. S. A.

Changes in the Medical Corps of the U. S. Army, for the week ended March 23, 1901:

- DE NIEDEMAN, Major WILLIAM F., surgeon, is relieved from duty with the Thirtieth Infantry, U. S. Volunteers., upon the departure of that regiment for Manila from its present station, for muster out in the United States, and will report to the commanding general, department of Southern Luzon, for assignment to duty in that department.
- TENNEY, Captain ELMER S., assistant surgeon, is relieved from temporary duty at the Army General Hospital, Presidio, and will report to the commanding officer, First Squadron, Fifteenth Cavalry, in camp on the Presidio, for temporary duty with that squadron, awaiting transportation to the Philippine Islands.
- PITCHER, GEORGE S., acting assistant surgeon, is relieved from temporary duty with the First Squadron, Fifteenth Cavalry, in camp on the Presidio, and will proceed to his home, Portland, Me., for annulment of contract.
- LEEPER, Captain MATTHEW, assistant surgeon, 7 days' leave granted March 7 is extended 15 days.
- TAKY-UD-DEEN, NAJIB, acting assistant surgeon, will proceed from Washington, D. C., to Columbus Barracks for duty.
- DILLON, G. PARKER, acting assistant surgeon, will proceed from Grand Rapids, Mich., to Fort Sheridan for duty.
- UNDERWOOD, FRED R., acting assistant surgeon, will proceed from London, Ohio, to Fort Leavenworth for duty.
- WILLIAMS, CHARLES F., acting assistant surgeon, is relieved from temporary duty at Fort Screven, to take effect upon the return to duty at that post of Acting Assistant Surgeon John R. Hicks, and will then proceed to Fort McPherson for duty.
- WHITNEY, Major Walter, surgeon, is relieved from further duty at Fort Walla Walla and will proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.
- McHENRY, Captain GEO. A., assistant surgeon, recently appointed, now on duty at Santiago, Cuba, will as soon as his services can be spared by the commanding general, department of Cuba, proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.
- ANDERSON, JOHN B., hospital steward, (appointed March 13 from acting hospital steward, hospital corps), Fort Mackenzie, is assigned to duty at his present station.
- RICHARDS, JOSIAH W., acting assistant surgeon, is relieved from duty on the transport "Buford" and will proceed from San Francisco, Cal., to Fort Mott for duty.
- WILLIAMS, CHARLES F., acting assistant surgeon, is detailed as a member of the examining board at Fort McPherson, vice Acting Assistant Surgeon Francis A. Halliday, relieved.

WERNER, MAX, hospital steward, Frankford Arsenal, Pa., will be sent to the Army and Navy General Hospital, Hot Springs, Ark., for treatment in the hospital.

PLUMMER, Captain GEORGE R., assistant surgeon, recently appointed, is relieved from further duty in the department of Cuba, to take effect when his services can be spared by the commanding general of that department, and will then proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.

WILLIAMS, ADRIAN D., acting assistant surgeon, now at Governor's Island, is relieved from further duty at Fort Adams and will report to the commanding general, department of the East, for assignment to duty with the first battalion of the Eleventh Infantry, and will accompany that battalion to the Philippine Islands, where he will report for assignment to duty.

SIMMEL, MARTIN, hospital steward, Columbus Barracks, is transferred to Fort McDowell, for duty with the hospital corps school of instruction.

Changes in the Medical Corps of the U. S. Navy, for the week ended March 23, 1901:

- PARKER, J. B., medical director, detached as president of medical examining boards, Washington, and ordered to the Naval Home, Philadelphia.
- MARMION, R. A., medical director, detached from Naval Home, and to duty at the Washington Navy Yard, as president of the examining board.
- MOORE, J. M., passed assistant surgeon, detached from the Port Royal Naval Station, and ordered to the "Franklin," April 2.
- BOBERT, E. S., passed assistant surgeon, detached from the "Massachusetts," and ordered home to wait orders.
- SHIFFERT, H. C., assistant surgeon, detached from the "Franklin," and ordered to the "Solace," April 1, and to the Asiatic Station.
- THOMPSON, J. C., assistant surgeon, ordered to the Port Royal Station.
- THOMPSON, E., assistant surgeon, detached from the "Nashville," and to the "Solace."
- HESS, H. H., ordered to the Naval Hospital, New York.
- GROVE, W. B., assistant surgeon, ordered from Naval Hospital, New York, to the Naval Hospital, Norfolk, Va.
- BRANSFORD, J. F., surgeon, retired in accordance with Act of Congress, approved February 5, 1901.
- RODMAN, S. S., assistant surgeon, detached from Naval Hospital, Mare Island, and to the "Adams."
- ORVIS, R. T., assistant surgeon, detached from the "Adams," and ordered to Naval Hospital, Mare Island.
- BOBERT, E. S., medical director, retired, detached from recruiting rendezvous, New York, and home.
- LAW, H. L., surgeon, retired, ordered to recruiting rendezvous, Buffalo, N. Y.
- CRAWFORD, M. R., surgeon, detached from recruiting rendezvous, Buffalo, N. Y., and to Marine recruiting rendezvous, New York City.
- LEACH, P., surgeon, detached from the "Oregon" and to the "McKenzie."
- EVANS, S. G., passed assistant surgeon, from the "Kentucky" to the "Concord."
- FARENHOLT, A., passed assistant surgeon, from the "Concord" to the "Oregon."
- HIGH, W. B. C., assistant surgeon, from the "Oregon" to the "Kentucky."

Changes in the U. S. Marine-Hospital Service, for the week ended March 21, 1901:

- McDOWELL, A. B., acting assistant surgeon, is granted leave of absence for 10 days. March 9.
- PECKHAM, C. T., surgeon, granted leave of absence on account of sickness, for 20 days from March 9. March 19.
- WOODWARD, R. M., surgeon, detailed as inspector of unserviceable property in the Hygienic Laboratory, Washington, D. C. March 21.
- NYDEGGER, J. A., passed assistant surgeon, to proceed to Norfolk, Portsmouth, and Newport News, Va., on special temporary duty. March 19.
- GARDNER, C. H., passed assistant surgeon, is granted leave of absence for 3 days from April 4. March 16.
- HOLT, J. M., assistant surgeon, Bureau order of March 8 is amended, and he is directed to proceed to Chicago, Ill., and report to medical officer in command for duty and assignment to quarters. March 20.
- WALKLEY, W. S., acting assistant surgeon, is granted leave of absence for 2 days. March 19.
- CARLTON, C. G., hospital steward, to proceed to Mobile, Ala., and report to the medical officer in command for temporary duty.

BOARD CONVENED.

Board convened to meet at Washington, D. C., on or about March 19, 1901, to examine Assistant Surgeon H. S. Mathewson, to determine his fitness for promotion to the grade of passed assistant surgeon. Detail for the board:—Surgeon P. H. BAILLACHE, chairman, Surgeon G. T. VANDERMAN, Passed Assistant Surgeon H. D. GEDDINGS, recorder.

Assistant Surgeons Appointed.—The Secretary of the Treasury has appointed the following as assistant surgeons, to serve during the quarantine season at the several fruit ports of Central America, their principal duty being that of inspecting fruit to be exported to the United States:

Bocas Del Toro, Colombia.—Paul Osterhout.
Port Limon, Costa Rica.—D. W. Goodman.
Livingston, Guatemala.—W. K. Fort.
Puerto Cortez, Honduras.—S. H. Backus.
Ceiba, Honduras.—R. H. Peters.
Belize, British Honduras.—J. G. Thomas.
Bluefields, Nicaragua.—W. H. Carson.

The appointees will serve in the office of the American consuls at the places mentioned.

Foreign News and Notes.

GREAT BRITAIN.

Elected.—Dr. R. B. Wild has been elected to the Leech professorship of materia medica and therapeutics at Owens College, Manchester.

Change in Editorship.—Dr. Henry Kellet has been appointed editor of the *Medical Press and Circular*, to succeed the late Dr. Archibald Hamilton Jacob.

Professorship of Surgery.—The professorship of surgery in the Royal College of Surgeons, Ireland, vacant by the death of Sir William Stokes, will be filled in April.

CONTINENTAL EUROPE.

Petroleum Drinking.—The Medical Society of Paris has expressed the opinion that it is necessary to adopt some measures against the alarming spread of petroleum drinking. At first, it was thought that this habit had sprung up from the increased taxation on alcohol imposed by the French government, but an investigation showed that this was not the case; the habit has been prevalent, some time previously, in certain districts, and had spread with great rapidity. The victim of the petroleum habit does not become brutal, only morose.

Marble Bust for the Discoverer of the Lepra Bacillus.—The sixtieth anniversary of the birthday of Dr. Gerhard Armauer Hansen, the discoverer of the lepra bacillus, will be celebrated on July 29, 1901. His numerous friends and admirers, both among the medical profession and the laity, will commemorate the occasion by the erection of a marble bust of Dr. Hansen in the Lungegaard Hospital, Bergen, where he discovered the lepra bacillus. A committee of Norwegians is active in the solicitation of subscriptions for this object.

Legislation for the Prevention of Malaria in Italy.—The *Lancet* publishes an account of the law drawn up for the purpose of preventing malaria in Italy. The articles provide for an official declaration of the affected areas, for the gratuitous distribution of quinin to the poor from municipal sources, and the taxation of property to raise funds. Another article compels the Government to supply quinin free of charge whenever it is responsible for the execution of a public work giving rise to malaria. The protection of all homes in the affected district against the entrance of insects and the empowerment of the Government to take any further measures necessary for the execution of the legal provisions, are included. In his new work entitled "La Malaria" Celli announces an annual mortality in Italy of 15,000 due to malaria, and that 5,000,000 acres of good land remain uncultivated.

MISCELLANY.

Kussmaul's Respiration.—This variety of respiration is characteristic of diabetic coma, and consists in a deep, abrupt inspiration, followed by a pause, then a quick expiration and another pause.

Medical Practice in New South Wales.—The *Western Medical Review* states that the new practice act for New South Wales calls for a term of 5 years' study of medicine. This would, therefore, exclude an American from practice because he is supposed to have graduated from a school of but 4 years. However, it seems that the first of the 5 years is similar to the last year usually spent in an American preparatory school before entering an American medical college, and the regulations of the British Medical Council says: "Graduates in the arts and sciences of any university recognized by the medical council, who shall have spent a year in the study of physics, chemistry, and biology, and have passed an examination in these studies for the degrees in question, shall be held to have completed the first of the 5 years of medical study."

History of Hospitals.—The institution of the hospital as we know it at the present day, with its regulations and rules, did not exist in the earliest times, nevertheless houses or establishments for the reception of the sick can be traced back to the early Jewish period. The earliest of these were known as Beth Holem, or houses of the sick; such a Beth Holem was Beth Saida, famous in the New Testament Scriptures. This institution was supported by voluntary contributions, as the word "Saida"—charity—naturally expresses. These hospitals were mostly situated round a pool, the waters of which were considered to be efficacious for various diseases, especially gout and rheumatism. According to the writer, the attendants in charge of these establishments were, as we know from the Scriptures (John 5: 2-7), expected to help the patients into the water. This kind of institution may be looked upon as the foundation of hospitals. They were, however, usually of a very primitive construction, mostly consisting of a few wooden huts.

In ancient Egypt hospitals were unknown, the sick being mostly attended to in their own homes, or, in the case of the very poor, at the various temples in the city to which they belong. The Greeks, however, appear to have been better supplied with institutions of this kind. Plato says that there existed in various parts of the country shelter houses for the sick. These institutions were, as Thucydides has observed, supplied with attendants, who waited upon the sick. It has been asserted that the ancients had no such attendants, because no pagan would wait upon a stranger in case of sickness; this, however, seems to be contradicted by the well-known case of the Samaritan (Luke 10: 30-35). Here was a man who had been attacked by thieves left by his own countrymen, and, moreover, priests, to die by the wayside, who was seen by a man of a country with whom his own kindred were at enmity. The foreigner seeing the man from Judea in trouble, not only attended him, but even helped him to mount his own ass. Many instances of a similar kind could be cited from ancient authorities. It is probable that the best hospitals of antiquity were those established in Rome. For some years it was doubted whether the Romans had such institutions, but a large tablet which was discovered near Placenza, dated in the reign of Trajan, has shown that not only did they possess such institutions, but that they were actually endowed. One of the earliest hospitals on record was probably that founded by Valens in Caesarea between the years 370 and 380 A. D.—[*London Physician and Surgeon*.]

The Good Effects of Methylene-blue in Acute Parenchymatous Nephritis.—N. Jabtat (*Sapisky Ekaterinoslawskago Medicinskago Ooshestwa*, 1900; *Vratch*, Vol. xxii, No. 4) reports 4 cases of acute parenchymatous nephritis, in which the methylene blue had a curative effect. The nephritis was secondary to scarlet fever. In one case, that of a girl of 7, the administration of the methylene-blue aborted what promised a severe attack of acute nephritis. In the other, that of a boy of 3 years, the usual treatment failed to improve the condition of the kidneys. The methylene blue, on the other hand, at once relieved the anasarca, and freed the urine from blood and, later, albumin. Similar results were obtained in the other 2 cases. The author treated 18 cases of scarlet fever and 6 of primary parenchymatous nephritis with this drug. The results in all were most gratifying. The beneficial effects of the methylene blue are explained by its chemical combination with the renal cells or the toxins generated by the microorganisms. [A.B.]

1.—Banks thinks that the actual cautery is at present too little used in certain surgical conditions. In syphilitic periostitis, where the pain is very severe, preventing sleep, and where the ordinary antisyphilitic remedies fail to relieve pain, he has found that the thorough application of the actual cautery will give permanent relief. The instrument should be at a white heat, and should be passed many times over the same tracks. In certain cases of arthritis, due to traumatism occurring in adults and not associated with tuberculosis, and in which rest, blistering, etc., have been of no avail, he has found the application of the actual cautery will give marked relief from pain and cause absorption of fluid. He gives a number of cases, illustrating the advantage of the actual cautery in this condition. In some spinal inflammations after injury, this method of treatment has also been of great advantage. Finally, Banks refers particularly to the use of the cautery in the treatment of pruritus ani. It is only to be recommended for this condition where the cause of the condition cannot be found and removed, and where other treatments have failed. He records a number of cases where patients have suffered from marked exhaustion from loss of sleep, produced by the itching, in which destruction of the affected skin by the cautery has given permanent relief. [J.H.G.]

2.—Between the ages of 20 and 45 years the blood-pressure is relatively high, the aorta and the other large arteries increase in diameter from the stress of the blood-pressure on their elastic walls, and the heart increases in size year after year at a nearly uniform rate. We have in these facts anatomic evidence of the great functional vigor and activity of the circulation in manhood. At 45, while the arteries continue to increase in circumference, the blood-pressure falls and the heart begins, almost suddenly, to diminish in size. These 3 features characterize the circulation for the next 20 years. This fall in the size of the heart is to be accounted for, partly by the widening of the arterial trunks and the consequent fall of pressure; and partly by the reduction of mechanical stress, due to comparative bodily relaxation, loss of vasomotor tone in the splanchnic area, and the chronic diseases from which the patient may suffer. The blood becomes more venous in quality and its hemoglobin value is lowered. At 65, the decline of circulatory energy and the effects of time on the protoplasm of the cells of the body have so lowered the metabolic and functional energy of the tissues and organs and the activity of the blood-supply that a considerable proportion of the capillary network becomes obsolete. The peripheral resistance is thus increased; the blood-pressure rises; therefore, the heart once more increases in size, so that at the end of 10 years it is found as large as it was at 45, and at the same time the hemoglobin value of the blood again proves to be higher. In other words, as age advances, the arteries naturally become wider, longer, and thicker, and altogether larger than in early life, and we must not speak of vascular degeneration in an evil sense as often as we find these conditions present. The heart may remain structurally sound, and is more often regular than irregular, to the most advanced years of life. Conversely, these facts suggest that actual diseases of the arteries and heart are not properly senile in their nature. Physical stress is a definite cause of cardiac and vascular damage in the second half of life, in the forms both of sudden, violent exertion and of ordinary

laborious occupations. Bruce has met with instances of acute and serious strain at all ages over 40, up to and even after 70. In some cases there was no reason to believe that the heart was other than sound before the strain; but in the majority of instances one or more of the safeguards of the circulation against strain were already defective or wanting. So far as the heart is concerned the principal safeguard is the presence of well-nourished, healthy cardiac walls. Two-thirds of the cases of cardiac strain in the second half of life presented a history of perverted metabolism. In many cases the occurrence of strain was but the latest of a series of similar events; the heart had been strained originally in youth or early manhood, and had given serious trouble as often as it was taxed again. Rowing or running at college was in a good many instances given as the cause of the first strain. Previous valvular disease, usually of rheumatic origin, is a condition powerfully predisposing to cardiac injury by physical exertion. Again, the metabolic disorders, including gout, that weaken the cardiac walls, are among the common causes of arterial degeneration, and the two influences, rheumatism and perverted metabolism, acting together no doubt are accountable for a considerable number of cases of atheroma and chronic arteritis. It is unwise, ill-timed, ill-planned muscular exercise that injures the circulation, usually on the part of the middle-aged man, who, awaking to the consciousness of growing fat and gouty, rushes inconsiderately to violent exercise for relief. Many cases of disorder and disease of the walls of the heart and arteries originate in distress, worry, anxiety, and protracted suspense; and the connection is most often seen in middle and advanced life because these depressing emotions fall most heavily upon mankind at this period. Alcohol undoubtedly plays an important part in many cases of cardiac failure that are regarded as due to overwork, worry, and nervous exhaustion both in men and in women. Many of the complaints of nervous depression, lowness, and worry are really due to gout and to influenza. Disturbances of metabolism, including gout, are by far the most prolific cause of cardiovascular disorder and disease after 40, at any rate amongst the middle and higher classes. Whatever the date of the primary infection, syphilis is a standing danger to the heart and arteries in the middle-aged man, and even in declining years. Acute and chronic diseases explain many cases, while the origin of other cases of cardiovascular disease is explained by the existence of emphysema and other chronic diseases of the lungs and pleura. Chronic Bright's disease threatens the function and structure of the heart and the arteries, and in many instances the different influences that threaten the circulatory organs act together in different combinations. There are some persons whose hearts and arteries cannot carry them through the wear and tear of what may be called everyday life for more than 40 or 50 years. This type of case is described as family heart, for it runs in families, 3, 4, 5, or more members of which may have all died suddenly of cardiac disease, some of them at an early age. [J.M.S.]

3.—See abstract for *Lancet* of March 9.

4.—In the course of over 6,000 microscopical examinations of urine from cases of nephritis, Estes has never been able to convince himself that he has seen the clear, flattened epithelial cells peculiar to the Malpighian corpuscles. He has been able to recognize the granular, rod-shaped epithelium of the convoluted tubules because the cells are polygonal with somewhat extended processes. The cubical or columnar epithelium of the latter part of the tubules is not difficult to recognize and is the kind most commonly found when renal epithelium is present. In a case in which urine from a carcinomatous kidney was examined there was an abundance of renal epithelium in the sediment. The epithelial cells did not appear isolated, as is almost invariably the case in tubal nephritis, but were frequently to be found in clumps, numbering from 4 to 20 cells, grouped together with some dovetailing; they were cubical in shape, granular in appearance throughout, except for a large and evident nucleus. These appearances pointed to rapid proliferation, and the tumor was a rapidly-growing carcinoma. There was much blood, a few blood-casts, and there was some renal pelvic epithelium. In cases of buried calculus the deposit usually contains blood, a few hyaline casts, no epithelial cells, although blood casts are present. In every case there was much free uric acid in the deposit, and the crystals were aggregated together. Epithelium

from the pelvis of the kidney was wanting or present only in very small quantity. Chemic examination showed the presence of more albumin than was accounted for by the quantity of blood present. **The epithelium** lining the whole of the renal pelvis and the upper part of the ureter belongs to the type of epithelium known as transitional. The cells of the deeper layer are those that are most easily recognized in morbid deposits, and the commonest forms present a rounded body with granular contents and an evident nucleus. The body usually tapers off rapidly into a prolongation, whose length may be twice or thrice that of the body. Some of these cells possess a prolongation at either end. They are only shed when there is extensive damage to the renal pelvis, and are most characteristic when that damage is due to mechanical causes, particularly the existence of a calculus in the pelvis. Blood and hyaline casts, and a slight though constant leukocytosis, not amounting to pus, with the almost invariable accompaniment of crystals. In cases of pyelitis due to causes other than calculus, the deposit contains casts, and when the pyelitis is due to any other infection than tuberculous, the urine contains numerous bacteria. The casts are broad, because they are derived from the ducts of Bellini and the collecting tubules, and sometimes they contain pus cells. In all lesions of the renal pelvis, whether due to calculus or not, it is usual to find more albumin than the microscopic examination seemed to warrant. The renal pelvis may contain neoplasms, and in such cases the deposit will contain groups of cells and isolated cells in large numbers, accompanied by blood. The cells will be of a most pleomorphic character, but usually are fusiform or spindle shape. **The disease of the bladder** that cannot be diagnosed by an examination of the deposit are very few. Cystitis can be distinguished from localized ulceration, papillomatous and epitheliomatous neoplasms recognized, and vesical calculus strongly suspected. In cystitis, the cells are usually derived from the surface of the epithelium. In epithelioma the cells are highly pleomorphic, smaller than in either diseases, but, on the average, larger than those of the renal pelvis; they tend to come away in groups, are granular, and contain a large and evident nucleus. But the most characteristic cells are found in cases of villous growth. The cells in these cases are of exceptional length, of a remarkable thinness, the greater thickness being that of the nucleus, with other cells which are shorter and more pleomorphic in the urine of lads between the ages of 14 and 20, clumps of clear, luminous, pear-shaped cells embedded in a mucoid material are often found. The author has never seen similar cells or groups of cells in urine from girls, so he believes they may be derived from the prostate. {J.M.S.]

5.—Smurthwaite reports the case of a man, aged 29 years, who was admitted to hospital in a semiconscious condition, with severe burns of the right hand and thigh. The patient was employed by the local electric works, where he had sustained the injuries. On admission, he was pale and almost pulseless, with pupils dilated, respiration very shallow, and extremities cold and clammy. His right hand and upper part of right thigh were very much burnt. There was a bunch of keys in his right trousers pocket, which were undoubtedly the indirect cause of the accident. The bunch was a very big one and bulged out the pocket so that the thigh was brought into contact with the screws in a water-contact switch, thus completing the circuit with the motor, which he was adjusting, producing the severe electric shock. {J.M.S.]

1.—The abstract will appear when the article is completed.

2.—Bramwell delivered a lecture before the Edinburgh Royal Infirmary on February 12, 1901, on **The statistics of gastric ulcer, with special reference to gastric hemorrhage, its frequency and fatality.** The author does not agree with Mr. Mayo Robson, as to the mortality of gastric ulcer and its frequency; and he fears that the mortality would be increased rather than decreased by operations for the arrest of hemorrhage in cases of gastric ulcer. Perhaps in no other disease are statistics so misleading as those pertaining to the subject of gastric ulcer, and the author believes that Mr. Mayo Robson has overestimated the total mortality and the mortality from hemorrhage in gastric ulcer. The frequency of gastric ulcer in the general population is estimated as being about 5% of the whole population (who suffer at some period of their lives). Bramwell states that this is probably an exaggerated estimate. The frequency of gastric ulcer is approximately arrived at in two ways: (1) By postmortem examinations; (2) from the clinical standpoint. The statistics collected by Welch show that out of 32,052 autopsies, gastric ulcers were found in about 5% of the number. The objections to the postmortem method are the following: 1. The frequency of gastric ulcer may be underestimated, because the stomach may not be opened in all cases. 2. Cicatrices of former ulcerations may be overlooked; the proportion of open ulcers to cicatrices is generally given as being 1 to 3. 3. It is questionable whether a superficial ulceration in the stomach, when healed, leaves a recognizable cicatrix, and the author mentions that there are cases of gastric ulcer presenting well-defined characteristic symptoms, which may heal without leaving any obvious or recognizable cicatrix. 4. Another objection to the postmortem method is that other lesions may produce scars; for example, syphilitic gummata and tuberculous ulcerations. The author concludes, therefore, that probably more than 5% of the cases collected and analyzed by Welch suffered from gastric ulcer. It is unreasonable to suppose that because 5% of the autopsies made in hospitals revealed ulcerations, that we should, therefore, conclude that this applies to the general population; postmortem examinations in hospitals are mostly made on adults, or, at all events, on individuals over 5 years of age; gastric ulcer is a very rare disease in early life (up to the fifth year). Therefore, it is unreasonable to suppose that because 5% of the autopsies in hospitals presented gastric ulcer, that 5% of the whole population suffers from this condition. The author states that gastric ulcer is very much more common in the class of patients found in hospitals, and that this condition occurs less frequently in the middle and upper classes, and probably to a less degree in the same class of persons living in rural districts. Hospital patients are, as a rule, drawn from towns; therefore, it would seem unreasonable to conclude that because 5% of the inmates of hospitals suffer from gastric ulcer, that the percentage is the same when dealing with the general population. Approximately, 13% of the general population is composed of children under 5 years of age; gastric ulcer being very rare in children under this age, and because autopsies are, as a rule, not made upon children, it is altogether unjustifiable to conclude, therefore, that because 5% of the persons examined postmortem in hospitals suffer from gastric ulcer, that the general community should be affected to the same extent. The death-rate from gastric ulcer in hospitals is much greater than the death-rate outside of hospitals; he concludes, therefore, that the estimate of 5% for the whole population is probably excessive. The frequency of gastric ulcer, as determined by the clinical method is less satisfactory than the postmortem method. The author gives a number of reasons for this; he has only observed 27 cases (or 0.44%),

out of 6,123 cases, seen in his own private consulting practice. It is extremely difficult to draw reliable conclusions as to the total mortality of gastric ulcer. If hospital patients form the basis of the calculation, the conclusions will be misleading, for the worst cases find their way into hospitals. The author mentions that, according to Mr. Mayo Robson, 81.25 (above 5 years of age), constitutes the annual mortality from gastric ulcer in Leeds (estimating the population at 500,000). An analysis of the number of deaths, which were registered from this cause in Leeds during the last year, showed that there were 14 deaths from gastric ulcer and 4 from hematemesis (probably due to ulcer), making a total of 18 cases; this is making a very liberal allowance. Estimating the population of Leeds as 500,000, 20.08 deaths would have been due to gastric ulcer last year. Bramwell believes that Mr. Mayo Robson's conclusions, regarding the total mortality from gastric ulcer in Leeds, must be incorrect. Bramwell also states that according to Mr. Mayo Robson, the deaths due to hemorrhage from gastric ulcer last year in Leeds amounted to 22.77. Upon examining the registration of deaths, he found that 8.1 deaths were due to hemorrhage. He believes that death from hemorrhage in cases of gastric ulcer is of rare occurrence; he only recalls a single instance in his own practice. [F. J. K.]

3.—See abstract of *British Medical Journal* of March 9.

4.—Harper advocates the use of pure urea in the treatment of tuberculosis, and believes the remedy to be superior to any other that is in use for this disease at the present time. The author's experience leads him to believe that more radical measures will be needed in the treatment of this disease than fresh air and the ordinary sanitarium, and that a careful revision of our diet list will form the keynote in the management of tuberculosis. Over one-half of his own cases of tuberculosis come from the country; therefore, it is hard to reconcile with the view that country air is the remedy for tuberculosis. He has urged tuberculous patients to partake of as much animal food as possible. The immunity of certain animals to tuberculosis may be ascribed to the character of their food; and in the author's opinion, urea and uric acid play an important part in rendering animals immune, or the reverse. The carnivora rarely become tuberculous, whilst the herbivora show a marked tendency to tuberculosis. The author finds, upon reviewing his notes of cases, that those individuals showing a marked tendency to gout, gravel and calculus very rarely suffer from tuberculosis. The negro, although leading an outdoor life, is especially liable to tuberculosis, probably for the reason that his food largely consists of starchy foods, such as rice, vegetables and fruits, and partakes sparingly of meat. The author applied the following treatment in his own cases: plenty of nutritious food, especially that rich in albumins (1 kidney well cooked, daily, with one half pint of beef tea); in carefully selected cases, he advised exercise in the fresh air; the medicinal treatment comprised drugs of recognized value, such as iron, cod-liver oil, hydrochloric acid, strychnia, pepsin, creosote, and urea has been added to the remedies mentioned. By partaking of a superabundance of rich food, containing a large percentage of urea, the tissues, and fluids of the body are rendered less susceptible to the invasion of the tubercle-bacilli; in short, they act as an antitoxin. A report of 9 cases of tuberculosis is given. In all of these urea was administered with very favorable results. The remedy is of special value when the disease is uncomplicated by various species of cocci. From the standpoint of a laboratory investigation, the author failed to obtain a growth of tubercle-bacilli in meat broth containing a small percentage of urea, whilst in the control tubes which did not contain urea the bacilli grew. [F. J. K.]

5.—Glasson reports an interesting case of pemphigus occurring on the third day after birth, in an otherwise healthy child. The disease first appeared as a bullous rash over the occipital region and then spread over the entire body, accompanied by fever, constipation and restlessness. Each spot was pricked with an aseptic needle, the child was kept in a warm rain-water bath for five minutes each day, and then anointed with boracic ointment. An interesting feature in the case lies in the fact that there is no history of syphilis in any member of the family and nothing to cause one to suspect this disease as being the cause of the pemphigus. The mother nursed the child throughout the entire attack.

During convalescence there was a complete exfoliation of the entire cuticle, leaving no blemish of the skin. [F. J. K.]

6.—McCardie reports 10 cases of ethyl chloride narcosis. He is very much impressed with the usefulness of this anesthetic. The anesthesia is produced in about 2 minutes and passes away in about the same time. It has no irritating action and can be administered in heart, lung, or kidney diseases where ether and chloroform are contraindicated. The only objection to its use is that complete muscular relaxation is difficult to obtain. McCardie uses the Breuer apparatus, which consists of a close-fitting mask with inspiratory and expiratory valves and a chamber above the former to hold the gauze on which the drug is sprayed. All the cases he has used it in have been short operations, such as the extraction of teeth, removal of tonsils, etc. [J. H. G.]

7.—Gray recommends as a local anesthetic in the ear, nose and throat a combination consisting of equal parts of a 20% solution of cocain in a mixture of equal parts of anilin oil and rectified spirit, and a 20% solution of eucain B in anilin oil. The latter is not a true solution, as eucain is only soluble to about the extent of 10% in anilin oil, therefore, before the solutions are mixed the eucain solution should be thoroughly shaken. Of the combined solutions he uses never more than 20 minims. Gray thinks that this combination of cocain and eucain in anilin oil is much more anesthetic than either of these drugs used alone, and much more so than an aqueous solution of them. He allows seven minutes to elapse after the application of the anesthetic agent before beginning his operation. Where chromic acid is used after the application of this solution the eschar will be of a dark green color, owing to the formation of an anilin dye. This, however, produces no deleterious effects. He never sees the intoxication from the use of these drugs which is not infrequent when used in aqueous solution. A blueness of the lips has sometimes followed the use of this anesthetic, but is never accompanied by any other symptoms. [J. H. G.]

8.—Newbold and Holland report two cases in which x-rays were used for the location of foreign bodies: one, a gun-shot wound of the face in which the bullet was easily located, and the other one of a plate with a single tooth which was readily located in the esophagus, and subsequently successfully removed through the mouth.

9.—Dalby calls attention to the great change which has taken place in recent years in aural surgery, showing that today the specialists, instead of discussing the minor ailments of the ear, are exercised over such subjects as cerebral abscess, thrombosis of the lateral sinus, mastoid inflammations, etc., and the wonderful advance made in the treatment of these conditions. [J. H. G.]

2. The Physical Examination of the Stomach. MARK I. KNAPP.
3. Infective Sigmoid Sinus Thrombosis. CLARENCE R. DUFFUR.
4. The Pathology of Intrauterine Death. NEIL MACPHERATTER.
5. Emphysema of the Eyelid from Nasal Causes. BEAMAN DOUGLASS.

1.—Harrison, in speaking of the advance made during the century in genitourinary surgery, mentions first the great improvement in the treatment of stone, brought about by the work of Bigelow of Boston. He remarks upon the completeness of Bigelow's work and how little improvement has been brought about in the operation of litholapaxy since its introduction. He refers to Rainey's views on the formation of urinary stone as being of the utmost practical importance. In discussing prostatic hypertrophy he urges that at least three varieties of this condition should be recognized and differentiated, as each requires individual treatment. The cystoscope here is of the greatest importance. The possible damage to the kidney, due to pressure from tension, is next taken up and Harrison suggests the possibility of relief in this condition from an exposure of the kidney, and incising its capsule. Lastly, reference is made to the progress of urinary antiseptics. [J. H. G.]

3.—Clarence R. Dufour presents an able paper upon **infective sigmoid sinus thrombosis**. The sigmoid sinus is more often affected with thrombosis than any other of the sinuses on account of its nearness to the middle ear, mastoid cells and antrum, cavities that are so liable to purulent inflammation. The etiology of this condition is by extension from chronic purulent otitis media, extension of thrombosis from other sinuses, traumatism such as a fracture passing from the base of the skull to the middle ear, infection from septic wounds of the head, neck or mastoid region and inflammatory secretion from throat or nasopharynx into the middle ear, antrum and mastoid cell. A large number of persons are affected with chronic middle ear disease, and it is from this class that a large number of cases of infected intracranial disease comes. The beginning of a thrombus of the sigmoid sinus rarely has any symptoms pointing directly to it other than the mastoid symptoms which demand the opening of the bone. There are no uniform or specific symptoms which determine the presence of a thrombosis of this sinus that may not vary in such a manner as to cause a doubt of the condition present. The writer regards the fluctuating temperature as important. The pulse rate is high—from 150 to 175—respiration soon becomes rapid and labored, vomiting and dizziness may or may not be present; meningitis may occur. When it does, these last two symptoms are usually present. The patient may become unconscious or delirious, or consciousness may be retained up to the time of death. There is often present an edema of the occipital region extending down the neck, which is caused by an obstruction of the occipital and mastoid veins, and by phlebitis of the same vessels. This is known as **Griesinger's symptom**, and when present is significant. Pain and pressure along the course of the internal jugular vein, and on the upper third of the posterior cervical triangle can often be elicited. Comparison of the two sides as to the degree of pain produced by pressure will often give valuable information when in doubt as to the condition of the sinuses. The most serious stage of the disease is that of the breaking down of the thrombus, at which time metastasis occurs. The writer closes with a detailed account of the technic of the operation. [T.L.C.]

5.—Beaman Douglass reports several cases of **emphysema of the eyelid from nasal causes**. The condition often results after a Bowman operation and the question then sometimes arises whether the surgeon is at fault. The condition may occur from any wound from the lachrymal duct as well as from disease when the wall of the lachrymal duct has been weakened. In an operation upon the lachrymal duct, if the wall of the duct is incised to such an extent as to permit a deep introduction of the knife into the wall, the cellular tissue around the upper wall of the duct is cut. If the patient subsequently blows his nose a rise of pressure causes air to be forced through the incision into the cellular tissue and into the wall of the eyelid. In operating the author advises the following precautions: Avoid as much as possible the use of the curet, never amputate any part of the middle turbinate during an ethmoid operation, as it subsequently can be removed if necessary. [M.R.D.]

Medical Record.

March 23, 1901. [Vol. 59, No. 12.]

1. 1. A Case of Ambulatory Typhoid Fever with Intestinal Perforation. 2. A Case of Traumatic Rupture of the Intestine; Operation; Recoveries. A. A. BERG.
2. Chronic Gonorrhea and Marriage. LUDWIG WEISS.
3. Excision of Aneurysm, with the Report of Two Cases of Femoral Aneurysm so Treated. GEORGE RYERSON FOWLER.
4. Conservatism in the Diagnosis and Treatment of Prostatic Hypertrophy. JAMES R. HAYDEN.
5. Subphrenic Abscess as a Complication of Appendicitis. J. McF. GASTON, JR.
6. Surgical Treatment of Abdominal Dropsy Following Cirrhosis of the Liver. JAMES T. JELKS.

1.—A. A. Berg reports a case of **ambulatory typhoid fever with intestinal perforation**, and case of **traumatic rupture of the intestine in which operation was performed**, and both recovered. The writer

has carefully studied the question of operation in cases of typhoid fever with intestinal perforation. His personal experience as to how major operations are borne by typhoid patients extends over three cases. He concludes that the early surgical intervention will show between nature's and man's surgical efforts such a marked difference in favor of the latter that the question of the propriety of operations for intestinal perforation with extravasation, occurring in the case of typhoid fever, will very soon be settled in favor of operation. As to operation in the **preperforative stage**, when our diagnostic acumen will have reached the highest stage of development, and when we are able to foretell an impending perforation, operation will clearly be indicated. But until then the writer agrees with Cushing that such symptoms of a localized peritonitis should place the attendant upon his guard so that the patient may be kept absolutely quiet, and tube omitted, especially if they are disagreeable and resisted. The necessity of calling in a surgeon in this stage of the course of the fever is urgent. The symptoms of the preperforative stage are local rigidity of the abdominal wall, usually an increased leukocytosis, local pain and tenderness of the abdomen, possibly nausea and vomiting, possibly an increased rise in the pulse and temperature. The symptoms of the perforative stage depend in almost all cases upon the extravasation of the cavity into the peritoneal cavity. With those rare exceptions in which a large blood-vessel of the intestine is eroded by the ulcer and in which the signs of internal hemorrhage are constantly present, the perforation per se does not give rise to any symptoms. If, however, the perforation is large, permitting of extensive extravasation, the reflex symptoms of shock will be very marked. They are collapse, fall of temperature, cold, clammy skin, rapid feeble pulse. The author concludes that it is of the utmost importance to examine the abdomen frequently for evidence of local rigidity and to make examinations of the blood every 24 to 48 hours. In patients with a distinct preperforative stage the sudden appearance of symptoms of shock when present clearly indicates perforation with extravasation. In those patients with a distinct preperforative stage, a decreasing leukocytosis and increasing abdominal rigidity with or without the previous signs of collapse demand immediate surgical interference. The author recommends a general anesthetic in those cases in which it can be borne. The existence of typhoid fever does not counterindicate an operation. The repair of the ruptured typhoid ulcer should be undertaken as soon after the perforation as the patient can stand the necessary laparotomy and possible eventration. Operation in the preperforative stage is not to be considered. Extravasation can usually be early diagnosed if strict attention is paid to the recognition of its symptomatology. [T.L.C.]

2.—Ludwig Weiss discusses the familiar question of **chronic gonorrhea and marriage**, and he concludes that we should only give permission to marry to those who have had gonorrhea when after repeated and careful microscopical examination of slide specimens and an exhaustive bacteriological and microscopical investigation of the threads and of the secretions of the prostate and seminal vesicles done under the strictest rules and with the aid of Graham's method the presence of gonococci cannot be demonstrated. [T.C.L.]

3.—George R. Fowler reports two cases of **femoral aneurysm treated by excision**. By means of this operation the vessel is ligated at its end instead of in its continuity, and by the process of ablation of the sac and the adjoining portions of the vessel provision is made against the two most active factors concerned in the relapse, namely, the existence of the portion of the diseased or injured vessel and the presence of one or more branches concerned in the recurrent circulation. One of the old-time dangers following ligation for aneurysm, namely, inflammatory suppuration of the sac and its consequent rupture with hemorrhage from collateral branches; following displacement of the clots at their points of communication with the sac, is rendered impossible by this operation. His first case made a good recovery and 3 years after the last operation has experienced no trouble. In the second case everything went on well until the end of the second day, when pulmonary congestion followed by a rapid edema terminated the patient's life. [T.L.C.]

4.—James R. Hayden discusses conservatism in the diagnosis and treatment of **prostatic hypertrophy**. He has been very forcibly impressed by the following facts: A

large number of patients now being operated upon whose symptoms judging from their recorded histories, hardly warrant such heroic methods, especially in these days of improved technic, as to catheterization and urethrovaginal irrigation as well as internal medication, improved soft rubber and woven catheters and the employment of local treatment to the prostate by way of the rectal route. **Hayden** points out the fact that in a large number of these cases of **prostatic hypertrophy** there is **considerable posterior urethritis, compressor spasm, urethrocystitis and true prostatitis**, with temporary swelling of the gland, and in these conditions much can be done in the way of palliative treatment. In those cases in which operative treatment is demanded the writer believes that the most satisfactory method is the partial or complete removal of the gland, either by the suprapubic, or by the perineal route, or by a combination of these methods. He does not believe that the **Bottini operation** will give as immediate and free vesical drainage as does prostatectomy, which is a strong argument against its general adoption. **Castration, vasectomy and ligation of the internal iliac arteries** are not to be recommended. [T.L.C.]

5.—J. McF. Gaston has collected a number of cases of **subphrenic abscess as a complication of appendicitis**, and reports a case of his own in detail. This complication is a very rare one. Many of the cases—there are some 45 collected—were not diagnosed until after the death of the patient. Pathological examination has shown that these cases may be extraperitoneal or intraperitoneal. Gaston's case had its onset on the first of June, when operation was performed. The recovery was complete on July 31. [T.L.C.]

6.—James J. Jelks discusses the **surgical treatment of abdominal dropsy following cirrhosis of the liver**. The operation consists of abdominal section preferably between the umbilicus and ensiform cartilage, evacuation of the accumulation of fluid, and scraping of the parietal peritoneum with a curette or rubbing off the epithelium with a gauze sponge. The superior surface of the liver and the peritoneum covering the diaphragm are also to be rubbed. The omentum for 3 or 4 inches around the incision is then to be stitched to the parietal wall. It is also included in the sutures which close the abdominal incision. Thus a broad surface is presented for adhesions, and it is this additional collateral circulation which has saved the patient operated upon. It is frequently necessary to tap these patients several times after operation, before the collateral circulation is complete. The writer believes that **all well-attested cases of cirrhosis presenting ascites** should be operated upon, and local anesthesia is recommended. He reproduces Frazier's table of 15 cases, his own being the fifteenth in the table. Three of these cases died within 2 weeks of the operation, 1 from contracted kidneys, 1 from septic peritonitis, and 1 from delirium tremens, who while delirious tore off the dressings and infected the wound. In discussing the results of the operations from Frazier's tables he shows that 75% of recoveries has taken place. [T.L.C.]

1. Retrospects and Prospects in Genito-Urinary Surgery. REGINALD HARRISON.
2. Cerebrospinal Meningitis (Weichselbaum, Jaeger) Treated by Repeated Lumbar Puncture. HENRY KOPLIK.
3. Drainage in Abdominal Surgery. J. W. LONG.
4. Vertigo; A Stomach Lesion. MARTIN A. H. THELBERG.

1.—Harrison mentions in his article on **retrospects and prospects in genito-urinary surgery** some of the prominent features in the progress of genito-urinary surgery: (1) litholapaxy, (2) Otis' urethrometry, (3) etiology of vesical calculus; (4) prostatic hypertrophy; (5) surgery of kidney. In prostatic enlargement he mentions 3 forms: (1) the simple enlarged prostate which bulges upward and backward into the bladder, more generally cured than any other form by castration, vasectomy, or by the Bottini operation; (2) a form in which a tongue of prostatic tissue, or a median lobe of the prostate, is the active agency that interferes with the emptying of the bladder. Castration and vasectomy, as a rule, do no good. The median tongue of tissue must be removed; (3) that form in which there occur in the midst of

the enlarged prostate hard glandular growths. Castration and vasectomy always fail, and also does Bottini's operation. He also suggests that for the condition of congestive tension on the kidney, an aseptic exploration with puncture of the capsule might easily be done without great danger and that this operation might serve as a prophylactic against the development of kidney disease in later life. [T.M.T.]

2.—Koplik in his treatment of **cerebrospinal meningitis by repeated lumbar puncture** gives the following facts: (1) Quacke method was employed and from 3 to 50 cc. of the fluid was withdrawn. The punctures were made on 5th, 6th, 8th, 9th, 10th, 13th, 16th, 19th, 24th, 28th, 36th, 37th days of the disease. The fluid withdrawn on the 5th day was turbid; on 6th, cloudy; on 8th, turbid; 10th, turbid and flaky; 13th, turbid, thick and purulent, and continued to be turbid up to the 37th day. This shows that there may be marked exudate even at an early period, and later puncture after chill may give a turbid, flaky, or even purulent-looking fluid. Councilman found in his examination that a diminution of turbidity went often hand in hand with absence of microorganisms. In Koplik's cases microorganisms were found in turbid, opalescent and less turbid fluids, and that also microorganisms grew in turbid fluids. In opalescent or clear fluids they were found by staining and sometimes were absent by culture. Only in one of his cases were the microorganisms absent by culture. On the other hand, they were positive in all stained specimens except one and in this the culture showed the diplococcus. It seems to Koplik that the difficulty of culture is rather the obstacle to a positive result, in some cases, than the abundance of microorganisms. In reviewing the treatment by the puncture, he found that such symptoms as persistent headache, somnolence, coma, delirium, and convulsions due to an accumulation of fluid in and about the brain and cord, and to a certain amount of toxemia resulting from the absorption of inflammatory products, were relieved for a time, at least. The puncture was carried out with antiseptic precaution, most of the patients receiving three punctures, although in one more were given. The operation was only performed when symptoms of pressure or accumulation of exudate appeared, and the procedure was only repeated if there was an exacerbation of the symptoms. If there was continued improvement, the patient was not disturbed, and by this method no harmful results appeared. There seemed to be no marked effect on the pulse and respiration, even if a considerable amount of fluid was withdrawn. [T.M.T.]

3.—In **drainage in abdominal surgery** Long states: (1) Objects of drainage; (2) objections to drainage. Drainage is employed (a) to drain away existing septic material; (b) to afford an exit for the sepsis when the operator fears that he has possibly infected his patient; (c) to provoke adhesions and thereby wall off weak spots from the remainder of the abdominal contents; (d) to keep the peritoneal cavity free of blood and other fluids; (e) to allow of a more certain knowledge of the conditions present in the abdomen; (f) gauze drains are sometimes employed as tampons to control hemorrhage. The objections are (a) it is deceptive; (b) cases not drained do better; (c) drainage is neither scientific nor workmanlike. [T.M.T.]

4.—Thelberg believes that **vertigo** is brought about by either or all of the following causes: 1. Reflexly through direct irritation of the gastric branches of the pneumogastric and thence by the lower cervical ganglion to the vasomotor nerves of the vertebral artery which supplies the internal ear. 2. By toxemia from amulon and other ptomaines, nicotin, alcohol, reabsorption, etc. 3. By direct pressure upon the heart through distention of the stomach and intestines by gases, resulting principally from so-called amyloseous indigestion and hyperchylia. Treatment, administration of a glass or two of hot water half an hour before meals, and some sodium bicarbonate before breakfast, and 3 to 5 grains of diastase with each meal, combined with strychnin, $\frac{1}{16}$ to $\frac{1}{8}$ grain, and in some instances a pepsin ferment. [T.M.T.]

1. Peerperal Insanity. ARTHUR C. JELLY.
2. Meat Rations in the Tropics. P. R. EGAN.

3. Bubonic Plague. Report on the Plague in Manila, P. I., from January 1, 1900 to June 30, 1900. JOSEPH J. CURRY.

1.—Two hundred and fifty cases of **puerperal insanity** were found on the records of the Institution's Registration Department of Boston, between 1872 and 1900. Jelly excluded 50 of these, so that 200 cases remained in which the puerperal state was the alleged cause of the insanity and in which the hospital records were at the disposal of the author. From an etiologic standpoint the cases may be divided into 2 groups: (1) those in which the puerperal condition appeared to be the sole cause of the insanity, and (2) those in which the preparations were already made and in which the puerperal state opened the door. Heredity is the great predisposing cause, although tuberculosis, alcoholism, epilepsy, hysteria, grief, fright, worry, domestic unhappiness, illegitimacy, sepsis, autointoxication, or several of these combined, play important parts in the etiology of the disease. In cases of gradual onset the first symptoms noted are a change of manner, so that the patient becomes somewhat indifferent and neglectful of the child and of her household duties. She grows reticent and her face shows a peculiar expression of watchfulness, as if she were anxious and yet unwilling to reveal her state of mind. Loss of appetite and inability to sleep occur early. Later, a patient may be confused, suspicious, resistive, depressed or, less often, excited; frequently she has impulses to suicide, or she makes attempts at suicide in an impulsive way; less often, impulses or attempts to injure the child are recorded. Hallucinations occur and distressing delusions are also recorded, which are frequently concerned with religion. After a short period many of the most excited cases become comparatively quiet and no longer suffer from hallucinations and delusions. Many septic cases are of short duration and end in death. Others improve after removal of the source of sepsis. Some cases of exhaustion live only a few days. Thirty patients had more than one attack. The prognosis as to life is very good. Of the 200 cases studied, 13 died in the first attack and 3 in the second; of the chronic cases, 14. The return of menstruation is a good sign, not because it in any way leads to recovery, but because it indicates a return to the normal condition on the part of the bodily functions. Recovery once well started usually progresses steadily. When the physician has reason to suspect the existence of conditions favorable to the development of insanity, he should instruct the patient to establish the most perfect hygiene possible in her home during her pregnancy, and if danger signals, pointing to instability, appear at any time, he should at once seek to remove the cause if possible, and endeavor in every suitable way to restore the balance. Special attention should be paid to the digestive and eliminative functions; exercise in the open air should be ordered; excitement should be avoided; and sources of annoyance should be removed. When mental disturbance appears after delivery wait until it is clear that the patient is suffering from something more than a mere temporary affair before deciding the question whether she shall remain at home or be sent away for treatment. In cases of profound sepsis or rapidly progressive exhaustion, death is liable to occur within a few days and it is especially unfortunate to remove such a patient to an insane hospital and have her die there in 24 hours. It is usually desirable and frequently necessary to separate the mother and child because of danger to the latter. Measures should be taken to prevent suicide, to maintain strength, to improve nutrition, and to insure sleep. It is usually necessary to give more or less alcohol. Hypnotics should be used freely if necessary and close attention should be paid to the functions of the bladder and the rectum. In the treatment of lactational cases nursing should be stopped and the attending debility and anemia should receive proper treatment. [J.M.S.]

2.—Dr. Egan's paper on the **meat ration in the tropics**, is a criticism of the statements made by certain army surgeons, that the soldier in the tropics should have the amount of fat and proteid in his diet reduced. [J.M.S.]

3.—For an early diagnosis of **bubonic plague** the most satisfactory method is that of aspiration of one of the recent swollen glands by means of a hypodermic syringe. With the material in the syringe: 1. A drop is used to make culture in melted agar tubes or in bouillon from which dilu-

tions, cultures, and plates can be made. 2. A drop is allowed to fall on a slide, which is then smeared by a platinum needle, to be used for direct examination. 3. The remainder is injected into a mouse or a rat. If examination of the specimens on the glass slides shows the presence of large numbers of characteristic, short, bipolar staining bacilli, that decolorize by Gram's method, the case at once becomes more than suspicious. By the second day the inoculated animal is either dead or very ill, and an absolute diagnosis can be made. In every instance in which the direct coverslip examination showed large numbers of short thick bacilli that decolorized by Gram, the subsequent history of the case, the cultures, and the inoculations of animals proved the case to be one of bubonic plague. In some cases bubonic plague is ushered in by a sudden chill, and this onset is followed by a fever closely simulating a malarial attack. If the examination of the blood in such cases fails to reveal the malarial parasite, but does show an early and marked leukocytosis, suspicion of a septic process of some kind should be aroused and the observer should look carefully for the cause of the leukocytosis. From January 1 to June 30, 1900, in Manila, there were 225 cases of bubonic plague with 167 deaths, a mortality of 74%. The right femoral and the right inguinal glands were the first glands to enlarge in considerably over one-half of all cases. It was unusual to be able to locate any fresh wounds of the extremity which appeared to be the point of entry of the infection. It was very common, however, to find skin lesions involving legs and thighs. There is the possibility of introduction of the plague bacilli through infection of these areas in which the epidermis is broken; as most people are right-handed, it may be possible that they are more inclined to scratch the right thigh than the left. Almost all cases of plague which came to autopsy showed evidence of bites by fleas and mosquitoes. It does not seem probable, however, that mosquitoes play any part in the dissemination of plague. Objection has been made by some to the puncture of a plague gland with the hypodermic needle. These observers claim that there is danger of infection by this method from rupture or injury of a bloodvessel which would allow the plague bacilli to enter the vessel and by it to enter the general circulation. Curry thinks that this objection to the use of the aspiration method for diagnostic purposes is based more on theoretic than on practical grounds. He believes it is much safer for both the patient and the operator than the incision method advocated by some. [J.M.S.]

1.—Grant reports several cases of **fracture at the elbow-joint** illustrated by x-ray pictures. These cases were all treated in the flexed position, which he thinks gives better results than in the extended position as recommended by Allis and Roberts. His article is illustrated by x-ray pictures of fractures occurring in other parts of the body, showing marked deformity, and yet the patients exhibited the most excellent functional results. In discussing the x-rays Grant calls attention to the great misconception which can be had

from examining skiagraphs of the injured part taken in different positions and by different operators. He thinks that it is a mistake to give the x-rays the prominent place which some have given them as a diagnostic and prognostic measure. [J.H.G.]

2.—Stillman discusses general bodily resistance as a factor in nose and throat diseases. As the cases coming to the specialist are usually chronic, the object of the treatment is to remove the effect of the long-standing pathological action. The author makes a plea for more constant study of the history of the patient in regard to the family history, the previous and personal history, and the mode of life of the patient and the environments, as well as the manifestations of the local disease. In order to properly advise and institute treatment, the specialist should always remember that he is a physician first and a specialist afterwards. [F.J.K.]

3.—Regarding the systemic factor as the cause of catarrhal deafness, Snow states that particular stress should be laid upon the following conditions: (1) Sluggish reaction of the skin; (2) low vital resisting powers; (3) torpid liver; and (4) improper exercise. For the sluggish reaction of the skin, which plays an important part in the etiology of catarrhal deafness, he recommends cold baths and friction. The problem of avoiding frequent colds, the author believes, is not to be solved by the excessive amount of clothing, but in stimulating the skin to proper and rapid reaction; lack of exercise, torpid liver, and digestive disorders also assist in the causations of catarrhal deafness. Many causes or conditions of causes participate in the production of this condition; therefore, the specialist should not only be well trained in the diagnosis of diseases of the nose, throat, and ear, but he should also have had a training as a general practitioner. Snow states that the prognosis should depend largely upon the physical condition of the patient and the ability to have skillful attention. While the surgical treatment is important, it is no more so than the proper attention to the functional equilibrium, especially after the operation. [F.J.K.]

4.—Randall states that, in order to come to the proper conclusions as to the diagnosis and prognosis of the ear diseases, a detailed family history should be obtained and the following objective findings added to the record: Ascertain the degree of hearing for whispered or conversational speech, for the tuning forks (use the forks which produce 50 vibrations per second, then 200, 500, and 2,000) and for the Galton whistle; also, test the hearing with the 200 fork by bone conduction (from the nose and mastoid bone); Politzer's test should be performed in order to determine whether or not the Eustachian tube is patulous, and for lateralization from the middle line; finally, otoscopic and rhinoscopic examinations must be made and the degree of response to inflation and pneumatic massage ascertained. [F.J.K.]

5.—Stern mentions that the effect of alcohol upon the nervous system is either direct (primary) or indirect (secondary). From a physiological or functional standpoint it may be either direct or indirect, and from a pathological or structural view it may also be primary or secondary. The author refers to a paper of Dehio, who has shown that acute alcoholism produces a diminution in the chromophilic granules of the nerve cells of the cerebral cortex, of the large multipolar cells of the spinal gray matter, and of the Purkinje cells of the cerebellum. Mention is made of a case which may bear relation to the observations of Dehio; this case was that of a lad aged 19, a farmer by occupation. The symptoms developed a year after he began the use of alcoholic beverages. The symptoms consisted of peculiar spasmodic seizures, which were motor in character and increased in frequency as the disease progressed. When the disease was at its height, the seizures occurred every few minutes and involved the greater portion of the body. Voluntary movements, however, were not markedly affected during the attacks. The deep tendon reflexes were somewhat exaggerated. After 9 weeks of treatment the patient recovered; the seizures gradually decreased in frequency and intensity and finally ceased altogether. The etiological factor was apparently alcohol. The changes of the nervous system, caused by chronic alcoholism, are secondary and depend upon vascular derangements. The author states that the chronic use of alcohol is a most important, constant con-

tributing factor of bloodvessel diseases. The author has long held the view that chronic alcoholism never develops unless a neurotic basis previously exists. He emphasizes the fact that the alcohol habit is a great social evil. [F.J.K.]

6.—McCaskey reports a case of combined gastric and aural vertigo. He concludes that, from the clinical point of view, the stomach must be regarded as a necessary cause in the reported case. He has observed several hundred cases of chronic gastric diseases, in which vertigo was a symptom. [F.J.K.]

7.—Upshur discusses heart-tonics in the broadest sense, from the standpoint of the clinician and therapist, rather than from a technical ground of physiological action. Heart-tonics are defined as remedies having power to regulate the action of the heart, whether due to functional or organic irregularities, or to that modification of its condition which produces a source of discomfort and danger to the patient. In dealing with the therapeutic value of digitalis, he emphasizes that this remedy in mitral stenosis is of transient benefit, and ultimately may be harmful in its results. In fatty heart, the danger of rupture of the cardiac wall is increased by its administration; its use is contraindicated in fevers, septicemia, and similar conditions; the pulse tension in pneumonia is not increased by digitalis. He refers to the dangers which follow its use in aortic insufficiency for reason of prolongation of the diastole, and the danger of rupture of the heart in aortic stenosis for reason of more forcible contraction of the ventricle during systole. Mention is made of the advantage of convallaria over digitalis, but the latter drug is more powerful and more reliable in its action. The slow elimination of spartein and for reason of its true stimulating action upon the cardiac muscle, makes it a reliable drug in the treatment of weak, flabby heart-walls. Strophanthus combined with strychnia is of value in the threatened heart-failure of enteric fever. The greatest benefit of atropin is found in tiding a patient over an emergency, such as sudden collapse, or threatened heart-failure; this drug should be combined with strychnia; he recommends caffeine for the dropsy due to parenchymatous nephritis, associated with heart involvement. Strychnia is placed at the head of heart tonics, its usefulness is especially manifested in the enfeebled heart of enteric fever, of pneumonia and of septicemia; nitroglycerin is indicated for angina pectoris (true or pseudo). It is contraindicated in the enfeebled heart due to septicemia and surgical shock. Under some circumstances, opium is a heart tonic. He mentions as an example the coma vigil of enteric fever, the aspect of the case may be greatly changed and a favorable termination depend upon the use of this drug. [F.J.K.]

8.—Osborne reviews some of the literature pertaining to organotherapy. He mentions the therapeutic indications for thyroid extract, thymus extract, pituitary extract and suprarenal extract. The important use of thyroid extract is found in the treatment of myxedema; it is contraindicated in Graves' disease, unless the patient is apathetic, sleepy, does not complain of headache and is gaining weight. Mention is made of its value in obesity, and such skin diseases as dry eczema or psoriasis. Thyroid extract seems to be indicated in certain cases of melancholia, in order to produce cerebral stimulation. The mental depression occurring at the time of menopause may, perhaps, be benefited by its administration. The author has used thymus extract in the treatment of Graves' disease and feels convinced of its value, but that it does not possess a curative action. Osborne mentions that it is fairly supposable that the administration of pituitary body extract in akromegaly can prevent the continued growth of the body and obviate some of the symptoms. The local action of suprarenal extract is positive, but the advantages derived by its internal administration are as yet doubtful. In Addison's disease it should always be tried for the possible good that might follow. [F.J.K.]

9.—Shoemaker reports a case of Addison's disease and discusses the treatment. He advises a trial of suprarenal extract in all cases. There is little hope in those cases of tuberculous origin; in the cases due to atrophy, sclerotic or inflammatory changes, if a portion of the gland is still active, suprarenal extract will probably be found useful. [F.J.K.]

10.—The abstract will appear when the article is completed.

11.—To be treated editorially when concluded.

1. Dysentery (in the Tropics): Its Symptomatology, Complications and Treatment. B. L. WRIGHT.
2. The Association of Chronic Jaundice with Gastroptosis. Report of a Case. J. DUTTON STEELE.
3. A Clinical and Histological Study of a Case of Melanosarcoma of the Chorioid. CHARLES A. OLIVER.
4. A Note on the Disinfectant and Deodorant Action of Ammonium Persulphate. M. P. RAVENEL and S. M. GILLILAND.

1.—B. L. Wright, assistant surgeon U. S. N., writing from the Philippines, furnishes us with a practical article upon **Tropical dysentery, its symptomatology, complications and treatment.** Dysentery, as met with in the tropics, is epidemic in character and most virulent in form. It seldom stops at the **catarrhal stage**, but rapidly passes to that of **ulceration**. If the patient does not die from exhaustion or complications the disease may slowly progress, finally becoming **gangrenous**. Wright believes that the cause is undoubtedly introduced into the intestinal tract by means of the drinking water, and in support of this generally accepted view describes an outbreak which was traced to neglect on the part of the cooks to boil the water which had been used after long transportation. For several weeks in which the water was boiled no cases developed. Immediately upon the cessation of this precaution the outbreaks occurred, and disappeared upon the condition being corrected. Another similar outbreak was traced to the contaminated water. In this case it was found that the sterilizer, which had been relied upon, was worthless. **Dysentery** in the Philippines begins usually with moderate fever, coated tongue and diarrhea. The character of the watery stools changes in the course of a few days to the mucous stool of the catarrhal stage. At this time griping pains in the abdomen are prominent. There is tenderness along the line of the colon, rectal tenesmus and frequent nausea. The stools are small, averaging about 4 grams in weight in number from 10 to 35 per day. **Gangrenous dysentery** is but a late stage of the acute condition. Wright calls particular attention to the fact that out of 30 cases of dysentery observed 3 developed **appendicitis** during the fifth or sixth week of the disease. [T.L.C.]

2.—J. Dutton Steele reports a case of **chronic jaundice associated with gastroptosis**. When the **gastroptosis** was corrected by fitting the patient with an abdominal support the signs of gastric insufficiency began to disappear quickly, and the jaundice also slowly disappeared. A study of the literature reveals no report of a case of **gastroptosis** unaccompanied by adhesions in which jaundice was present. From a number of experiments performed upon a number of bodies, Steele found that while the descent of the **pylorus** alone cannot produce obstructive jaundice, if the ducts are bound down by adhesion to the under surface of the liver a very moderate degree of traction produced by a displaced pylorus might bring about such a result. In the case in question Steele concludes that there were some conditions causing a **perihepatitis** or some form of **peritoneal inflammation**, and that adhesions bound down the common or hepatic ducts in such a manner that the apparently slight amount of traction from the prolapsed stomach caused kinking, obstruction and jaundice. [T.L.C.]

3.—Charles A. Oliver reports a clinical and histological study of a case of **melanosarcoma of the chorioid**. The patient presented a nodular mass of the left eye which could be seen protruding between the widely opened eyelids. The nodule, which was somewhat mobile, was vascular and pigmented. Its internal surface was covered with numerous scabs beneath which bleeding areas could be exposed. The skin of the lower lid was excoriated and excreted a thin, sanious fluid. The mass was painless, and the right eye was normal in every respect. The orbital contents were removed and the patient made uneventful recovery. A very careful microscopic examination of a large number of sections from the removed mass was made. The preponderance of the cells over the intercellular substance, as is usual in such growths, the gross infiltration into the surrounding tissues and the thorough destruction of all the soft ocular elements are of the utmost importance. The long period of time,

possibly more than 26 years in this case, that the growth had been in existence and the almost certain surety of the failure of extension or metastasis for a period of more than 3 years' time after the removal of the orbital mass are of great importance in the prognosis of such an affection. [T.L.C.]

4.—Ravenel and Gilliland have conducted a series of experiments upon the **disinfectant and deodorant action of ammonium persulphate**. They conclude that it has little, if any, value as either. [T.L.C.]

4. A Digest of Recent Literature Upon Perforation of the Intestine in Typhoid Fever. JOHN J. JOFSON.

1.—Francis R. Packard contributes a noteworthy historical article upon **General Joseph Warren**, one of the leading medical lights of his day, and a staunch patriot. This is the first of a series of twelve articles on medical men prominent in the civil and military affairs of revolutionary times. It is replete with anecdote and characterized by evident historical accuracy. [T.L.C.]

2.—J. William White reports a case of **evulsion of the second and third division of the gasserian ganglion** for the medical treatment of **trifacial neuralgia**. White states that the etiology of the condition, as in his case, is too often hypothetical, or absolutely unknown. The medical treatment should include the removal of the reflex sources of irritation, though well developed it is rarely found to have such origin. **Dana** divides the period of treatment, as to curative value, into two cases: First, a neurotic type occurring early in life, affecting women much more often than men, running a long, tedious course with no tendency to recovery allied to ordinary migraine and due probably to central disease—a disorder of the sensory neuron—and not to disease of the gasserian ganglion. The second, a more common type, occurs later in life, after the age of forty, affecting men at least half as often as women, sometimes beginning as a definite, infective neuritis, and a disease either of the peripheral nerves or of the ganglion. In the first classification **Dana** believes that operative procedure is of no avail. In the second class he maintains that nothing short of a complete removal of the gasserian ganglion will produce anything more than temporary relief, and this, he urges, may also be secured by medical means. **White**, however, believes that in men cases of tic which have resisted medical measures for from six months to a year should be regarded as requiring surgical interference. Operations on the peripheral nerves are likely to do good, when the disease is distinctly limited to either the second or third division of the nerve and where the evidence shows that there is a peripheral neuritis. In view of the atrophy of the cerebral center which must follow the excision or destruction of the nerve trunk peripheral operations might still effect a cure even if the cause were central. The intracranial operation may be considered as a primary operative procedure in those very severe cases affecting all the divisions of the nerve with frequently recurring paroxysms and with no immediate relief from medical treatment. **White** recommends Cushing's modification of the Hartley-Krause operation as the method of approach. He believes that this method will reduce the present mortality of 20% and will increase the percentage of cures 90%. The surgeon may limit his interference to evulsion of the second and third division between the ganglion and the foramina, knowing that this has been followed by cure in a number of cases. This course of action is favored by the knowledge that primary and exclusive disease of the first division has never been known to occur. There is also less risk of injury to the

abducens nerves and to the cavernous aversus sinus, and by leaving the first division untouched diminishes the later danger of trophic changes in the eye. The latter course of treatment was followed in a case which White now reports and the patient was free from pain 11 months after the operation. [T.L.C.]

3.—Charles H. Frazier and M. H. Biggs publish a preliminary report on the value of the tuberculin test in the recognition of latency, or quiescence, in tuberculosis of the bones and joints. The object of the investigation was to determine solely whether tuberculin could be employed to advantage, not as a means as revealing the presence of a focus in the incipency of the disease, but as a means of determining whether the disease has apparently run its course and subsided, whether the process is in a state of quiescence, of latency, or whether resolution with total disappearance of all tuberculous material has occurred. Carefully prepared tables are furnished by these writers showing the results of the reactions they have obtained. The table of positive reactions is deserving of attention; of the "recovered" 78%; of the "quiescent" 100%; and of the "active" 80% responded in a positive manner. Those cases in which for periods varying from one to seven years there had been no clinical evidence of active tuberculosis gave positive reaction. Some of the patients classified as "recovered" had submitted to a radical operation for the removal of the affected joint, or the affected area in the bone. The writers inquire "what is the interpretation of the figures these tables supply?" They might be accounted for in one of 3 ways: (1) The general unreliability of the test; (2) misinterpretation of the clinical phenomena; and (3) the existence of tuberculous foci elsewhere. The first supposition may be ruled out. The positive reaction in answer to (2) might be accounted for by the presence about the seat of the old tuberculous disease of small areas in which were imbedded the bacilli of tuberculosis in a dormant state. It is possible that these minute areas might account for the positive reaction. The existence of tuberculous foci elsewhere than at the seat of the so called primary bone and joint tuberculosis may be relatively frequent. For instance, in the intrathoracic or intraperineal chains of lymphatics. The positive reactions which are obtained, therefore, in so large a percentage of cases that have recovered would seem to vitiate the value of the tuberculin test when employed for the demonstration of the presence or absence of tuberculous lesions in other tissues of the body. [T.L.C.]

4.—John H. Jopson supplies a digest of recent literature upon perforation of intestine in typhoid fever. This is based upon 7 recent papers which have appeared upon this subject, those by J. M. T. Finney, Harvey W. Cushing, W. W. Keen, J. Collins Warren, G. G. Davis, William Osler, and H. A. Hare. [T.L.C.]

The Journal of Nervous and Mental Disease.

February, 1901. [Vol. xxviii, No. 2.]

1. A Case of Cortical Sclerosis, Hemiplegia and Epilepsy, with Autopsy. CHARLES L. DANA.
2. Diffuse Degeneration of the Spinal Cord. JAMES J. PUTNAM and E. W. TAYLOR.

1.—Dana gives a summary of his case of cortical sclerosis, etc., as follows: Child, aged 4½ years, forceps delivery, right hemiplegia from birth, general epilepsy from six months, operation, death, meningeal thickening, general cortical sclerosis in area of distribution of Sylvian artery, atrophy, degeneration of pyramidal tract, no degeneration of lemniscus or atrophy of cerebellum, considerable deficiency of tangential fibers. This case, he states, furnishes a contribution to the pathological anatomy of infantile hemiplegia with epilepsy and helps to throw light upon the origin of, at least, some cases of this disease. He also mentions lesions which are found causing similar conditions: (1) Diffuse sclerosis; (2) Lobar sclerosis; (3) Atrophic sclerosis; (4) Hypertrophic sclerosis; (5) Porencephaly; (6) Agenesis; (7) Cysts; (8) Simple atrophy. These various anatomical defects have as a cause (a) simple developmental defects; (b) chronic hydrocephalus; (c) meningo-cephalus; (d) vascular lesions, such as hemorrhage, embolism, thrombosis of veins and inflammatory lesions such as polioencephalitis. The author thinks

that in the case mentioned the anatomical defect is atrophy due to a vascular defect or disease and that during intra-uterine life, partial stoppage of the left middle cerebral artery and its branches leading to the incomplete development of the brain which it nourished. The obliteration could not have been complete without leading to a more massive and localized lesion. [T.M.T.]

2.—In 5 cases of diffuse degeneration of the spinal cord studied pathologically by Taylor, the features common to the general group of lesions were: 1. A diffuse degeneration for the most part limited to the cord, often in more or less discrete patches. 2. A constant involvement of the dorsal and lateral columns, without strict regard to neurone symptoms. 3. A predominance of the lesion in the cervical and thoracic regions. 4. The common freedom from degeneration of nerve-roots, both motor and sensory, and of peripheral nerves. 5. The practical noninvolvement of gray matter. 6. Insignificant vessel-changes. Putnam and Taylor's general conclusions derived from the study of this condition are: 1. That a well-defined lesion of the nervous system particularly localized in the cord exists, which may for the present be termed simply "diffuse degeneration." 2. That no fundamental characteristics of the lesion have been found depending on different causes. 3. That anemic states have been shown at times to be a concomitant condition, but not necessarily a cause. 4. That actual causes are still wholly obscure. [T.M.T.]

7. The Influence of Soil on the Prevalence of Pulmonary Phthisis. ARTHUR NEWSHOLME.

3.—Perkins discusses the facts which lead the larger life assurance companies to accept so few women as risks. In the population at large the average mortality for women is about two per thousand less than that for men—a difference largely due to the protection from the occupation risks to which men are liable. This difference is not equally distributed through the whole period of life, as between the ages of 5 and 35 the mortality between the two sexes is nearly equal, while from 10 to 20 years the deaths are more numerous among women. Among assured lives, however, the reverse holds, instead of a less mortality a marked excess over the death-rate among men is found up to the age of 45 and 50, due partly to incomplete medical examination, partly to the motive for assurance. The increased mortality among women before 20 is largely due to phthisis, which has an earlier age incidence among women than among men, and from the early age has little interest for assurance purposes. After 20 the increased mortality among women arises from the accidents of childbirth. Between the ages of 25 and 45 childbirth is held accountable for nearly one in ten of the total deaths of women, and if the deaths from this cause were removed the mortality would fall well below that of men. The death-rate for married women is less than for the unmarried except at the age when the risk of childbirth is the highest. As to cancer the evidence of heredity is much stronger in females than in males. Perkins sums up by concluding that the death of the mother from cancer requires a substantial increase in premium. If one other female relative has been affected the risk becomes serious and in some cases prohibitive. The death of a male relative from cancer is less serious, but no female life with a well-established family history of cancer should be accepted at the ordinary rate. [T.M.T.]

7.—Arthur Newsholme contributes an exhaustive paper upon the theory of the influence of soil on the prevalence of pulmonary phthisis. He has made a careful study of the death-rate in various towns in Great Britain

in which there were different degrees of drying of the sub-soil. His statistics, which are based upon a comparative study of the death-rate before and after proper sewage facilities were introduced, suggest a number of considerations. It appears probable that much of the benefit ascribed to the drying of the soil has really been due to other factors of improvement. Buchanan's results show the benefit of altitude in lowering the mortality from phthisis, even when the permeability is the same at the two levels. It may be that as the dry soils are usually higher than the wet, altitude may be as important a factor as dryness of site of house. Holland, for instance, has been already mentioned. It has been very malarious and yet not excessively phthisical. Indeed there is a widespread impression that ague is antagonistic to phthisis. The fact that such a widespread impression exists and that ague is most common in marshy districts does not support the view that there is a causative relationship between phthisis and wet soil. Newsholme concludes that personal infection is the main cause of the spread of phthisis, and that this occurs chiefly where people are most closely agglomerated and live an indoor life. That deficient nutrition is an important favoring cause of **phthisis**, and that wetness of soil operates in a minor degree by favoring catarrhal conditions of the respiratory mucous membrane. [T.L.C.]

8. Operations in Acute Intestinal Obstruction. SINCLAIR WHITE.

3.—Hellier reports three cases of this very uncommon condition and gives the following important facts: The incision of an imperforate hymen to evacuate retained menses is beset with serious dangers and that antiseptic methods have not diminished the danger. He states that the most serious danger arises when the hematosalpinx is present as well as hemato-colpus and hematometra: (a) the thinned out, distended oviduct has often contracted adhesions, and may rupture when the great mass of accumulation is liberated; (b) the hematosalpinx is apt to become septic. This is due to the fact that it does not contract and empty. A hemato-colpus can be easily drawn and irrigated. A distended uterus contracts well, but a distended oviduct has little power to expel its contents. Hence, if hematosalpinx is present it is better to perform abdominal section and to remove the tubes. Their removal greatly improves the patient. [T.M.T.]

5.—In reporting two cases of acute yellow atrophy of liver, Hall concludes that yellow atrophy of the liver seems to be due to a toxin formed, possibly in the alimentary canal, but as to its origin or nature very little is known. The likeness of symptoms to those in cases known to be the result of toxic action, such as phosphorus poisoning, seems to suggest similarity in origin. Jaundice is probably due to a catarrhal inflammation and consequent obstruction of the smaller ducts, caused, possibly, by secretion of the irritating toxin "toxemic catarrh" (Hunter). What relation, if any, such cases bear to various cases of cirrhosis of the liver is unknown. The treatment is to check the formation of toxin in the alimentary canal by intestinal antiseptics and keep up the patient's strength. Diagnosis is generally not made until symptoms of the last stage have commenced, when treatment is of no avail. [T.M.T.]

6.—Menzies notes in his case of calculous pyonephrosis: (1) Complete absence of hematuria throughout the course of the case; (2) no history of the passage of gravel;

(3) pain not paroxysmal; (4) pain not influenced by exercise; (5) pain not especially referred to the affected side; (6) long period of tolerance (6 years) before the advent of alarming symptoms. [T.M.T.]

1.—Part 1. (See Editorial.) Part 2. Klebs is of the opinion that **inhalation tuberculosis** is very rare. In between 4,000 and 5,000 autopsies he was able to discover but one instance, which occurred in a young girl, who had nursed a tuberculous patient. He thinks the reason for this is that the tubercle bacilli are very rapidly killed by drying. Certain experiments that he has undertaken prove this fact conclusively. He believes that the frequent involvement of the apices of the lungs is probably due to original lymphatic infection. He also believes that laryngeal tuberculosis may arise in the same way. [J.S.]

2.—Frank has undertaken a number of experiments in order to determine the efficacy of **alcohol as a disinfectant**, as it was necessary to discover some disinfecting agent that, in the form of gas, would disinfect brushes, hair, etc., with certainty. He found that in the various preparations of alcohol, those with a higher specific weight have more energetic disinfectant action. As a matter of fact, the most energetic preparation is 40% alcohol, which boils at about 90° C. He believes that in addition to the disinfection of various objects requiring penetration, alcohol may also be useful for hygienic purposes, such as the disinfection of houses, etc. [J.S.]

3.—Engel, as a result of careful studies of the red blood-corpuscles in cases of anemia, particularly in view of the fact that the non-nucleated red blood-cell is derived from the nucleated cell of the marrow, believes that we are able to predicate **four types of bone marrow as a cause of the blood-changes**. First, normal bone marrow in which the blood contains only the normal ortho-chromatic erythrocytes; second, the insufficient bone marrow characterized by excess of nucleated red cells with the following changes in the blood. Normal number of red cells, with diminished hemoglobin, that is chlorosis; or the diminished number of red cells with proportionate or disproportionate diminution of hemoglobin; or, occasionally, pathologic red blood cells of normal size showing peculiar color reactions, and occasionally nucleated. Third, metaplastic bone marrow of the red or embryonal type. All types of abnormal red blood-cells are found in the circulation. Fourth, the aplastic bone marrow characterized by nothing but fat even in the epiphyses. The red blood-cells are normal, but rapidly diminish; granulated leukocytes are absent. [J.S.]

4.—Dennig reports a case of **leukemia** in a girl, 19 years of age. There was marked leukocytosis, and an excessive number of mononucleated cells. The red blood-

cells were diminished. The patient had all the characteristic symptoms of leukemia, with the exception of enlargement of the spleen and lymph glands. Death occurred, and at the autopsy all the organs were normal, both macroscopically and microscopically, and even the bone marrow showed no alterations. [J.S.]

5.—Mertens reports the case of a woman, who at the age of 15 had had a severe attack of coughing, followed by an expulsion of a yellowish-white membrane, and a considerable quantity of clear blood. This attack was repeated several times, and from time to time there were also attacks of severe hoarseness, blisters upon the lips and tongue, and occasionally ulcers upon the skin that healed very slowly. When admitted to the hospital it was observed that she was pale, not very well nourished, there was a patch of membrane in the throat surrounded by an area of hyperemia, and a few ulcers, bluish in color, and covered with a membrane, were found in various parts of the body. The tonsils were always intact. Very rarely blisters appeared in the mucous membranes of the mouth that apparently contained no micro-organisms, that is to say, on only one occasion was a culture obtained of the staphylococcus aureus and smear preparations were always negative. On one occasion, the patient had an attack of acute edema of the larynx. Treatment was entirely useless. Local applications of chromic acid appeared to produce improvement but it was temporary. A diagnosis was made of **chronic pemphigus**. An interesting feature was the presence of numerous cysts in the skin beneath one of the affected parts. The differences between the lesions in the mucous membranes and the skin were also remarkable. [J.S.]

6.—Tiedorpf, after considering the desirability, on various grounds, of an exact definition of character, suggests the following: "We speak of a diseased character in cases in which all or some of the psychical qualities present in a human being, in as far as these, either as conscious or as unconscious factors, influence the inner psychical activities and the external actions, have either undergone some change as a result of disease, or have been influenced previously by disease. The morbid changes, or perhaps better, morbid influences, may affect the number, the intensity or the variability of the relation of the qualities of the character; or the mutual relations of the qualities of the character to one another." This he regards as a considerable improvement upon the previous definitions. [J.S.]

7.—Port reports the case of a man 40 years of age who developed appendicitis followed by considerable accumulation of pus in the perityphlitic space. It was decided to evacuate this through an **incision alongside the anus**. By careful dissection it was possible to reach the abscess cavity, and about $\frac{1}{2}$ of a liter of pus was evacuated. The incision was 10 cm. deep, funnel-shaped, and therefore readily cleaned. Several days later a large fragment of necrotic tissue was expelled, and thereafter granulations filled the cavity very rapidly, and in the course of 4 weeks the patient was discharged entirely well. [J.S.]

8.—Quaddieg reports an interesting case. A woman of 44 **swallowed** her plate containing 2 **artificial teeth**. She felt severe pain in the thorax, but daily explorations with the esophageal sound failed to reveal any obstruction. An examination with the Röntgen-rays apparently showed a mass in the small intestines. As the condition of the patient became alarming an exploratory incision was made followed by gastrotomy, and the removal of the plate from the esophagus through the cardia. There was considerable bleeding, and a gastric fistula was left which was subsequently cured by another operation. [J.S.]

9.—Zervos reports 6 cases of **echinococcus of the liver**, all of which **ruptured into the lung**, causing death in 5 cases. In the sixth case there was severe coughing with an expectoration containing numerous echinococcus cysts. The patient, however, recovered. In 4 of the fatal cases the diagnosis was confirmed by autopsy. All these cases were previously operated upon by the method of capitonage, and the author draws the conclusion that this operation is not only useless but actually dangerous, because after the occlusion of the cysts by suture, new ones are formed, and meeting dense scar tissue anteriorly, usually extend in the direction of least resistance, that is toward the convex surface of the liver, and eventually rupture through the diaphragm. [J.S.]

1. On the Etiology of Acute Articular Rheumatism. MENZER.
2. A Contribution to the Etiology of Hay Fever. C. DIETSCH.
3. Operating During the First Ether Anesthesia. P. SUDECK.
4. The Operative Treatment of Pulmonary Tuberculosis. H. SARFERT.
5. Concerning the Decomposition of Albumins by Boiling. K. OPPENHEIMER.
6. Pathology and Treatment of Cicatricial Contraction of the Bladder. A. ROTHSCILD.

1.—Menzer first reports his own work, which consisted in the discovery of **streptococci in the joint exudate** in 2 cases of rheumatism, and in the tonsils in 3 cases. His method of investigating the tonsils was to excise a portion, and to make bacteriological examinations of the cut surface, thus looking only for bacteria that were present in the substance of the tonsil. The bacteria found produced inflammation of and exudation into the joints in animals, and in some cases caused endocardial changes. He then discusses the work reported by Meyer in the last number of the same journal, and directs attention to the fact that the discoveries reported by Meyer are by no means new, for there have been repeated reports of the presence of streptococci in the joints and in the tonsils in rheumatism. The streptococcus discovered by Meyer differed in some ways from that found by Wassermann, and the one which Menzer reports also showed some variations from either of these. The conclusions which Menzer reaches are, that the discovery of streptococci in rheumatism is by no means new, but this does not mean that it is entirely without importance. It is true that one can find streptococci and staphylococci frequently in almost any infectious disease, and particularly in the mouth and throat; in the latter places even under normal circumstances. The importance of certain streptococci is, however, that they tend to cause joint changes in animals. He considers it a question whether we shall ultimately find streptococci to be the sole cause of rheumatism; also whether the streptococci which are at times found on the normal tonsils will prove always to lack the peculiarity of producing joint changes in animals. He considers it impossible as yet to make any definite statements concerning the bacteriology of rheumatism. A number of forms of bacteria have been discovered, chiefly streptococci, staphylococci, and pneumococci, and some of these have the power of producing joint changes. It is possible that some one of these changes may be shown to be the actual and constant cause of typical rheumatism, though this is certainly questionable considering the close relation of typical acute rheumatism to rheumatoid and pyemic affections. From a clinical standpoint, however, rheumatism seems to Menzer to present the characteristics of a morbus sui generis. [D.L.E.]

2.—Dietsch discusses the two chief theories of the causation of hay fever,—the one being that it is due to constitutional factors and irritation, the other attributing it to infection. Those holding to the theory that it is spread by infection belong to two classes; certain authors consider that it is spread by dust, pollen, etc., which carry the infection; others that the infection is not related to pollen, etc., but that these latter bodies act merely as irritants, and prepare the way. Dietsch gives a review of the reasons for considering that pollen is actually connected with the causation of the disease. He strongly holds to this belief because of the occurrence of the disease almost entirely at the period when pollen is present and plants are blossoming. There are many points against the view that the disease is due to infection. In the first place fever, if it occurs, is very slight. Second, the sense of smell is almost always uninvolved; the contrary is often true of other infections which involve the nasal cavities. Further, infectious diseases which continue for years practically always leave behind some important sequels. There is absolutely no evidence of any sequel in hay fever, or any involvement of other organs than the respiratory. Also the predisposition to the disease is so peculiar that it could scarcely be the result of an infection. Some persons are predisposed to

the disease for life, while the great majority of persons have absolute immunity. If it is infectious, there must be an enormous possibility of infection, since the predisposed regularly have the disease, and under such circumstances it would be extremely peculiar if those who were not greatly predisposed did not occasionally acquire the disease and subsequently as well as previously remain free from it. He thinks that the disease is a catarrh resulting from mechanical, chemical and thermic irritation of the nasal cavities, which is predisposed to by a general sensitive ness of organism, irritability of the nervous system, prolonged nasal catarrh, and probably arthritism in the parents. [D.L.E.]

3.—Sudeck states that there are a number of operations that can be performed in a short time but in which **local anesthesia** is not applicable. He recommends in minor operations, and the more serious ones that can be quickly performed, the employment of the very first stage of ether-anesthesia. The following points are to be observed: 1. The patients are instructed to take deep inspirations at the beginning of ether-administration. 2. The patients should be impressed with the fact to concentrate their minds upon the anesthesia. The instruments should be kept from the view of the patient and the latter should be kept in ignorance of the fact that the operation is soon to be performed. 3. The operation should be immediately performed at the first or second ether-inhalation and should last but a few minutes. The advantages of this method of anesthesia are the absence of danger, prevention of disturbances to the respiratory organs, and the rapid recovery from the narcosis. [M.R.D.]

4.—H. Sarfert believes that there are many cases of pulmonary tuberculosis that can be benefited by **surgical procedures**. The author has experimented upon 150 cadavers, and finding that apical cavities are best reached by the operation by resection of the second rib, proposes the following operation: An incision is made into the skin at the external extremity of the rib and is extended outward about 4 inches. An incision is made into the periosteum, the cartilage cut through and an entrance obtained at the axillary end. The parietal pleura is separated from the chest with the fingers. The apex of the lung is brought out without opening the pleural cavity. An opening is obtained into the cavity either by the knife or Paquelin cautery. Exposed bloodvessels may now be ligated and several communicating cavities should be opened and the whole converted into one cavity. In one of the author's cases where the size and extent of the cavity were determined by palpation and the above operation performed, the hectic fever and hemoptysis ceased. [M.R.D.]

5.—Oppenheimer briefly reports that bottles of milk stopped with cotton or rubber, and containing hanging from the top filter paper which had been moistened with acid of lead were heated for various lengths of time. After sufficient heating there was always a brown discoloration of the lead paper indicating the **presence of H₂S**. This he considers a definite demonstration that the albumin of the milk was broken up with the heating. Boiling the milk for 5 minutes gave an extremely slight reaction. The reaction was distinct after 10 minutes and increased after this time. It was very marked after 20 minutes. The importance of this in connection with sterilization of milk is evident, and a further discussion of the matter will appear elsewhere. [D.L.E.]

La Semaine Médicale.

January 30, 1901.

1. The Application of the Method of "Sufficient Dose" in the Treatment of Some Maladies of the Nervous System: Those Grave Forms Associated with Migraine, Menière's Vertigo, Neuralgia and Tic douloureux. DR. GILLES DE LA TOURETTE.

1.—This paper presents studies upon the method of treatment originally expounded by Charcot, based upon the administration of **sufficient dose of bromid** in epilepsy. Having determined the personal equation of the patient by the establishment of his point of toleration for the bromid, a dose is maintained for a period of time which is found to be sufficient to lessen the **cortical motor excitability**,

and to cause the disappearance of the attacks. The treatment was originally used in epilepsy, but the writer believes that it has equal value in **Menière's vertigo** and cases of severe **neuralgia and tic douloureux**. The author first discusses the treatment of **grave forms of nervous disorders associated with migraine**. It is applicable to all forms, from the simple migraine to the severe types with accompanying scintillating scotoma, hemiopia and even transitory aphasia. A case is reported of a young woman of 34 years, who had suffered for a long period from attacks which lasted 3 full days of each week, compelling her to remain in bed and to abstain from all food. After some 5 months of treatment by the bromids there was a great improvement. The second case is a patient of 58 years, who had suffered for a long time from a grave **migraine** accompanied by a **right hemiplegia** after a very severe attack, which disappeared after 8 days' treatment with **bromid of potassium**. This case was followed for 2 years, the patient took progressively increasing and decreasing doses of bromid. There was a gradual restoration to health. His third case was one of **ophthalmoplegic migraine** in a young man of 35 years. A cure was brought about by prescribing rapidly increasing doses of bromids up to 7, 8 and 9 grams. The pupillary phenomena from this treatment showed themselves in the third week. Regarding the treatment of Menière's vertigo, he believes with Charcot that the disease depends upon a **hyperexcitability of the labyrinth** analogous to corticomotor excitability, and he reasons that as bromids lessen the latter condition, **sulfate of quinin** ought to suppress the labyrinthine hyperexcitability. **Quinin** is given to the point of toleration, then the dose is decreased and finally increased again. After a period of 2 or 3 months, sometimes longer, a complete cure will be brought about. For the treatment of **tic douloureux**, he recommends .06 cm. of **extract of opium** per day. This is increased every day or every other day by a pill of .02 cm. and the point of toleration will indicate when sufficient dose has been attained. The toxic influence of the drug must be carefully watched. In the first period of treatment 30 to 40 cm. may be given in from 5 to 7 days, after which time it is necessary to increase it with care. The patient should be carefully guarded against cold and the chamber kept at an equal temperature. After this first period the dose should be diminished daily and very gradually. [T.L.C.]

February 6, 1901.

1. Typhoid Fever Simulating Appendicitis. Operation. Death. M. RENDU.

1.—The patient was a young woman of 29 years who entered the hospital having suffered from a headache for 5 days. There were no abdominal symptoms or vomiting, but there was a loss of appetite, and an evening rise of temperature. She had suffered from **typhoid fever** at 5 years and a **grave metritis** at 19. After several days there was pain in the **right iliac fossa** and a diagnosis of **salpingitis** was tentatively made. Rest, injections of permanganate of potash, applications of hot compresses over the abdomen, a semi-solid diet and the application of several leeches over the painful region improved her condition. The temperature fell to normal. For several days the **aprexia** was complete. Then the temperature suddenly rose to 39.6 C. There was vomiting and abdominal tenderness as well as profound induration in the region of the appendix. Operation was performed, but the appendix was found to be perfectly normal. The patient's condition continued to grow worse and death ensued. A postmortem examination showed the case to be one of **typhoid fever**. The **Widal reaction** had not been employed. [T.L.C.]

February 13, 1901.

1. On the Assimilation of Inorganic Preparations of Iron and their Role in the Treatment of Chlorosis. A. JAQUET.

1.—Jaquet furnishes us with a comprehensive resumé of the studies made during the past 25 years as to the value of the various organic and inorganic iron preparations. With reference to **chlorosis**, experience has proven the good to be derived from certain organic preparations, but he recom-

mends in our present state of knowledge that the preparations of the pharmacopeia be employed rather than many of the much vaunted "assimilable" preparations which lack the test of time to determine their value. [T.L.O.]

Journal des Praticiens.

February 9, 1901. [15me Anné, No. 6.]

1. A Case of Tuberculous Nephritis, with Epileptic Convulsions and Sudden Blindness. CHAUFFARD.
2. Symptoms of Lithemia in Children. JULES COMBRE.
3. Convulsions with Hemiplegia in an Infant of 15 Months. LE GENDRE.

1.—Chaufard reports the case of a woman aged 32 years, whose urine contained albumin for the three years prior to her death. She had had a miscarriage, with retained placenta, double phlebitis, and peritonitis, and repeated attacks of bronchitis, earlier. **Typical epileptic convulsions** occurred as often as twice a week. There were edema of both legs, ascites, edema of the lungs, and a slight pleural effusion. The left ventricle of the heart was hypertrophied, and there was marked **arteriosclerosis**. In the urine were **albumin, granular, fatty, and hyaline casts**. The day after admission, she suddenly became blind, and had a very severe convulsion. After being bled 700 grams, vision returned. The ascites increased, and she died of edema of the lungs, after 600 grams of liquid had been withdrawn from her abdomen. The autopsy showed the right kidney weighing 15 grams, while the left weighed 150 grams. Both were sclerotic. In the left were some hypertrophied tubules, still able to function, while none were found in the much-atrophied right kidney. Chauffard considers the **convulsions uremic**, and the sudden loss of vision due to inhibition of the cortical optic centers by the uremic convulsion. The renal condition, he calls **tuberculous nephritis**. [M.O.]

2.—The **lithemic diathesis** is generally **hereditary**. Among the many manifestations of gout (arthritis) seen in children, Combre enumerates pallor, anemia, enlarged lymph-glands, convulsions, headache, neuralgia, neurasthenia, coryza, epistaxis, spasmodic laryngitis, asthma, adenoids, palpitation, arrhythmia, functional murmurs, syncope, edema, gastrointestinal symptoms, jaundice, albuminuria, enuresis, glycosuria, rheumatism, urticaria, eczema, and many more. Then he calls particular attention to three other symptoms: (1) **Periodic headache**, severe, coming on suddenly, without other symptoms; (2) **cyclic vomiting**, severe, sudden, lasting days, with fever, and followed by headache; and (3) **arthritic fever**, intermittent, quotidian, with no suspicion of malaria. To explain all these different symptoms, Combre mentions that there are probably grave autointoxications in lithemia. As treatment he advises rest in bed, baths, and injections of normal salt-solution. All children of gouty ancestry should be brought up in the open air, with exercise, and massage. They should drink much water, and eat little meat, but many vegetables. Meals should be regular. They should have no alcohol. Alkaline waters should be given from time to time. [M.O.]

3.—A baby of 15 months, **hereditarily syphilitic**, suddenly had **convulsions**. They were epileptic in character, the right side moving more than the left. Right hemiplegia followed, more marked in the leg. Sensation remained normal. Babinski's reflex was present. Both pupils were contracted. Le Gendre gave two grams of mercurial ointment externally, and one gram of potassium iodid in rectal injection, daily. For two weeks treatment was of no avail, then the convulsions ceased. From that time the child improved continually. The **cause of the convulsions** was undoubtedly **syphilitic**, a gumma, a circumscribed meningitis, or encephalitis, in the left Rolandic region. [M.O.]

1. Corporal Punishment in Russia in the Twentieth Century. D. N. SHBANKOW.
2. The Public Importance of Skin Diseases. O. W. PETERSEN.

3. On the Injection of Sodium Cinnamylate in Tuberculosis. L. A. FINKELSTEIN.
4. On the Question of Determining the Oxidizability of Water by Means of Permanganate of Potash. A. Ph. DRSHEWETSKY.

2.—Petersen shows how infectious skin diseases are widespread in Russia, and recommends as a prophylaxis the infusion of the knowledge of hygiene into the masses as well as the establishment of public baths constructed on modern sanitary principles. [A.R.]

3.—Will be abstracted when completed.

4.—Drshewetsky points out an error in the determination of oxygen consumed in water, hitherto unnoticed, namely, the oxidizing properties of the salts of chlorine and bromine. As a result of carefully conducted experiments, he arrives at the following conclusions: 1. In determining the oxygen consumed by means of permanganate of potash, a correction should be made for chlorine by deducting 0.15 mg. of oxygen (per litre) if the permanganate solution is normal, and a corresponding amount if weaker than normal. 2. This correction can only be made with waters containing not more than 0.1 gm. of chlorine per litre. 3. The salts of bromine oxidize permanganate of potash according to the following equation: $2\text{HBr} + \text{O} = \text{Br}_2 + \text{H}_2\text{O}$, i. e., in proportion of 160:16. 4. The determination of organic substances in mineral waters rich in salts of chlorine and bromine is impossible. [A.R.]

1. On the Question of the Significance of the So-called Paralytic Chest (Thorax Paralyticus). I. G. GABRIELOVITCH.
2. Corporal Punishment in Russia in the Twentieth Century. D. N. SHBANKOW.
3. On the Injection of Sodium Cinnamylate (Natri Cinnamyllici) into Tuberculous Patients. L. A. FINKELSTEIN.

1.—Gabriellovitch has made the tuberculous chest, or the "paralytic chest," of Engel's, the subject of special study. He justly considers the chest measurements hitherto applied unreliable, inasmuch as they vary considerably with the individual. Much more accurate he finds the relative measurements between the chest and other parts of the body in the same individual. To establish the normal average, he took the measurements of 31 perfectly healthy individuals between the ages of 20 and 30, the mode of life and occupation being nearly the same in all. The measurements taken were as follows: (1) Height; (2) the circumference of the chest on a level with the nipples, both at inspiration and expiration, only the median being noted; (3) the circumference of the abdomen on a level with the umbilicus, both at expiration and inspiration, only the median being noted; (4) the length of the trunk from the upper border of the sternum to the pubes; (5) the antero-posterior diameter on a level with the fifth dorsal vertebra, and the lateral diameter on the same level (by means of a pelvimeter). Having thus determined the normal average, the author subjected to the same measurements 75 tuberculous patients of about the same conditions and stage of the disease, none of them being very far advanced. The results are tabulated, as follows:

RELATION.	HEALTHY PERSONS	TUBERCULOUS PATIENTS
Of the circumference of the chest to the height . . .	1:1.8	1:2.0
Of the circumference of the chest to the circumference of the abdomen	1:1.8	1:2.0
Of the circumference of the chest to the length of the trunk	1:0.62	1:0.67
Of the lateral to the antero-posterior diameter	1:0.70	1:0.75

It is thus seen that the tuberculous chest may be characterized as long and narrow, the circumference being equal to half the height. The narrowing, however, is lateral instead of antero-posterior, as is commonly believed. The "paralytic chest," as described by Engel, Rokitsansky, and others, is, according to the author's observations, rare in the first and second stages of the disease. [A.R.]

3.—Will be abstracted when completed.

Original Articles.

ATMOKAUSIS: ITS VALUE IN THE TREATMENT OF SEVERE AND UNCONTROLLABLE UTERINE BLEEDINGS (UTERINE ARTERIOSCLEROSIS).

By SAMUEL W. BANDLER, M.D.,
of New York City.

PROF. SNEGIRJOFF, in Moskau, has for years used steam at a temperature of 100° C. in controlling uterine bleedings. In his opinion steam cauterizes, stops hemorrhage, removes every odor, and diminishes the sensitiveness of the inner lining of the uterus.

Pincus introduced this method into Germany. His first experience was with an inoperable corpus carcinoma, with endometritis hyperplastica, and with endometritis cervicis, obtaining good results. Since then the method has been used on many sides and for quite a series of gynecological affections. Kahn used this procedure in many cases of septic postpartum endometritis with very quick benefit. He found that the sensitiveness of the uterus was diminished and that good contractions resulted. The steam had a bactericidal effect and the disagreeable odor disappeared. Through thrombosis, the blood- and lymph-vessels were closed and a protecting cover was formed for the development of fresh granulations. Clinically, temperature fell, usually by crisis. Only in those cases where action was delayed, or where placenta or membranes were retained, did an immediate improvement fail to result. Pincus obtained good results in putrid abortions and in climacteric hemorrhages where abrasio failed, in subinvolution uteri and gonorrheal infections. In the clinic of Pawlik, in Prague, about 50 cases were treated with this method and with excellent results, especially cases of abortion with large bleedings due to atonic uteri, and chronic hemorrhagic endometritis.

Dührssen also has used this method for some time, and it is my purpose to prove the value of this method, for my results were uniformly excellent. The improvements which Dührssen made in the apparatus used for this purpose are undoubtedly responsible, in a great measure, for the good results. Originally, Pincus used metallic catheters for the intrauterine introduction of steam. Later he added a tube which permitted the outflow of the liquefied steam. Since the metal tubes caused deep cauterization and stenosis of the cervix, through direct contact of the hot catheter, he used gauze to protect this part of the uterus. Later he used tubular wooden plates to protect the lining of the cervix from cauterization.

Unfavorable results were reported, among others, by Czempin, who mentioned an atrophica uteri with climacterium præcox in a patient who, 6½ months postpartum, was treated by this method for a hemorrhage lasting 8 weeks. A death was reported from the clinic of Traube, due to necrosis and perforation of the uterus resulting in peritonitis. V. Weiss recorded an obliteratio uteri in a nonpuerperal case treated for continued uterine bleeding.

These failures and poor results occurred for the following reasons:

1. The introduced catheter permitted no outlet for the vapor, so that a continued action of the same resulted.

2. The heated metal catheter caused a deep cauterization, through direct contact with the cervix and uterus.

3. On contraction of the uterus the tip of the metal catheter exerted a local and deeply cauterizing action.

The advantages of the apparatus of Dührssen are as follows:

1. The uterine tube consists of fiber stuff which does not transmit heat, so that the cervix is protected.

2. This tube is centrally perforated and its lumen is so large that when the metal tube through which the steam enters the uterus is introduced there is sufficient room for an outflow of steam and coagulated blood.

3. This metal tube, through which the steam passes, does not come in contact at any point with the mucous lining of the uterus.

I have used this method mostly for bleedings which could not be overcome by other methods. Frequent cases were climacteric bleeding where our purpose was to cause a destruction of the endometrium with resulting obliteratio cavi. At the same time the future development of a corpus carcinoma is in such cases impossible. A dilatation of the cervix is a preliminary in all cases, not alone to permit of an easy introduction of the uterine tube and to furnish subsequently good drainage, but also to permit of a tactile examination of the uterine cavity in all cases. In one case, treated for continued bleedings, in spite of the good results obtained by this method in other patients, I was compelled to perform a hysterectomy uteri. These are the cases where the natural sclerosis of the uterine vessels during climacterium reaches a very high grade. In general this method is absolutely specific for these forms and especially valuable when other means fail. What is the pathological condition in such a case? Bleeding?

In gynecological hemorrhages, if such from the vulva, vagina and portio vaginalis be excluded, visible bleedings are limited to the cervix and the uterus. Acute infections cause a certain amount of hemorrhage, but large losses of blood from the cervix are due either to carcinoma, sarcoma, myoma, or polyps, conditions easily diagnosed on proper examination. The intact lining of the cervix does not bleed, taking no part in menstruation. An affected lining of the cervix bleeds less frequently than the lining of the corpus uteri, for it takes but slight part in the physiological swelling of menstruation.

Bleeding from the corpus uteri may be due to local conditions, to affections of the adnexa, to general physical disturbances, to nervous or temporary circulatory phenomena. The only normal uterine bleeding is menstruation. Every very strong menstruation or every irregular bleeding must be viewed as pathological. If the uterus on examination be found enlarged the following conditions must be looked for: myoma or sarcoma of the uterine wall, carcinoma, sarcoma or polyp of the endometrium, chronic metritis with endometritis, the complications of pregnancy, such as endometritis, placenta prævia, abortion, retention of placenta or decidua, trauma, subinvolution. If the uterus be not enlarged, there may be present endometritis or a malignant change or degeneration of the endometrium. If, on examination with a sound, the inner lining feels smooth and even, the endometrium is probably normal. Of the secondary hemorrhages from the uterus, a not infrequent cause is acute pyosalpinx. In this category, above all, extrauterine gestation must be taken into consideration. Bleedings due to tumors of the ovary are rare, and if they do occur are the result of bilateral tumors, especially carcinomata. The peritoneal causes of uterine bleedings come under the head of pelveo-

peritonitis in that case the associated endometritis is the probable cause. This holds true likewise of the bleedings complicating parametritis.

Among the other forms of decided uterine hemorrhage, the most important are the so-called bleedings of menopause. At the climacterium a gradual disappearance of menstruation, becoming less and less at each period, is rare. Without a previous diminution in the amount of blood lost periodically, the menses, as a rule, are absent for one or two periods, they then return at the regular time, usually increased. The interval between the individual bleedings is rarely more than five or six months. The loss of blood as a rule does not reach a dangerous height, but these bleedings may occur often and last long. We may have at first a too early appearance of increased menstruation, and then later a delayed appearance of increased menstruation. In other cases there is a constant oozing of blood until the next flow appears. Even after a disappearance of menstruation for half a year or a year a bleeding may again occur, so that it is difficult to say when a final cessation has taken place. In such cases endometritis, myoma and carcinoma must be excluded, for if after an absence of six or more months a bleeding occurs, it should be considered pathological until proven otherwise. Not infrequently there occur at the natural climacteric age, and likewise much earlier, the so-called climacterium præcox, most decided and long-continued bleedings, for which no apparent cause can be found.

We have at the menopause hemorrhages without decided changes in the endometrium, and without the presence of new growths. The bleedings are frequently stopped with difficulty and recur. These often continue in spite of rest in bed and the use of stypticin, hydrastin, ergotol. Even curetting and tamponing have no effect, and not so very rarely hysterectomy is necessary. Why do these profuse bleedings occur, and why is this condition found in younger women? What is the cause, what is the treatment? This form of decided hemorrhage is due to local uterine trophic changes caused by a cessation of function on the part of the ovary and its secretion. Even though the only symptom is profuse hemorrhage, since the same changes are found in the uterus in unexplainable bleedings in younger women, we must view these later cases as climacterium præcox. The pathological cause of these bleedings is the uterine arteriosclerosis.

Halban found that castrated newly-born guineapigs showed no future development of the genitalia, and no development of the uterine muscle. Knauer found, after castrating rabbits, that the uterus atrophied, and that the intermuscular connective tissue was increased. Sokoloff castrated dogs and found that the uterus, especially the circular layer, became atrophied, the vessels were thickened and their lumen smaller. Jentzer and Beutner, on castrating cows, found an atrophy of the muscle and of the glands of the uterus, an increased growth of the connective tissue, and changes in the stratum vasculare. Glaevecke and many others have found that after castration the uterus of women atrophies. Benkisser found that the vessels of a uterus, removed 3 months after castration, showed a sclerosis and an endarteritis obliterans. Eckhardt found, one year after castration, that the uterus of a woman was atrophied, the endometrium likewise, and that the connective tissue was increased. Gottschalk found 1½ years after castration that, although the muscle of the

uterus was well retained, the mucosa was atrophied and that the large vessels showed a folding of the intima. Therefore, after castration, the changes are like those occurring at the menopause. At and after menopause the uterus undergoes regressive changes, the portio shrinks, and we have the so-called senile uterus. The wall is thin and dry, contains much connective tissue; the vessels are thickened, narrow, and calcified. The mucous membrane is thin, flattened, and indurated. This change occurs likewise in younger women, and is due to an early cessation of ovulation and functional activity on the part of the ovary, and is therefore an early senescens, so that in climacterium præcox we have an early atrophy of the uterine genitalia, often going hand in hand with increasing obesity. Why this early change in the ovary should occur in certain cases we do not know, for in our discussion we exclude those atrophic conditions resulting from acute infectious diseases. Do these normal changes at climacterium, and do increased changes of this kind in individual cases explain the irregular and profuse hemorrhages in some patients, and the uncontrollable hemorrhages in others? The recent investigation of Pick upon the amount and character of the elastic fibers of the uterus throw decided light upon this question.

Under the serosa, or peritoneal covering of the uterus, is a subserosa which is absent, however, at the fundus and on most of the corpus uteri, the peritoneum being for that reason very adherent at these points. A membrane of elastic fibers is found under the serosa (or under the subserosa) which separates it from the outer muscular layer of the uterus; this membrane at times lies under the external muscular layer or both above and below it. From this membrane go out the elastic fibers found in the two outer muscular strata. Between the uterine serosa and the mucosa we distinguish four layers of muscle-fibers: *A*, the stratum subserosum, longitudinal; *B*, stratum supravasculare, longitudinal, and circular; *C*, stratum vasculare, the main layer, with its fibers arranged circularly and about the vessels; *D* stratum submucosum, longitudinal. As said before, the elastic fibers of *A* and *B* are derived from the membrane of elastic fibers usually found under the serosa, while those of the stratum vasculare are derived from the elastic fibers of the adventitia of the vessels. In the stratum submucosum the elastic fibers are few in number. The elastic fibers of *A* and *B* run at right angles to the muscle fasciculi, *i. e.*, the muscle-fibers run up and down, to the right and left, while the elastic fibers run dorsoventrally, *i. e.* radially, sending out anastomosing branches in all directions. They thus form a framework or a collection of septa, like the fingers of the two hands crossed at right angles. The vessel anastomoses run up and down, and the elastic fibers, the muscle-bundles and the vessels therefore cross in a longitudinal, transverse, and sagittal direction. In the cervix there is no such framework. We have here two layers, one under the squamous epithelium, the other about the vessels; these layers communicate. It has been said that a disappearance of the elastic fibers is responsible for rigidity of the cervix. It is, however, really due to a disappearance of the muscle elements, and to their replacement by sclerotic connective tissue, so that rigidity is present in spite of the elastic fibers.

The ends of the elastic fibers of the uterus run between the muscle-bundles, upon the surface of the bundles; they may surround a fasciculus or they may perforate it. In the stratum vasculare, where the elas-

tic fibers come from the adventitia, finer fibers are found in the interfascicular connective tissue, but most of these are not connected with the main fibers. They are sometimes absent in the virgin uterus. Elastic and fibrous tissue, situated between the muscle-bundles, sends branches between and around every muscle-cell, but always at right angles to the long axis of the cell. The individual muscle-cells of the stratum subserosum have therefore a perimysium elasticum, and a perimysium fibrosum; the muscle-cells of the stratum supravasculare and the stratum vasculare have a perimysium fibrosum and often a perimysium elasticum. The fibers of the stratum submucosum have only a perimysium fibrosum. The important muscle fasciculi are thus furnished with a framework or elastic support which protects the fibers from over-stretching and permits their return to normal position on contraction. This elastic framework is especially well developed in the outer layer and permits any change of form on the part of the fibers. We thus have a perimysium interfasciculare and pericellulare. The circumcellular perimysium of the strata supravasculare and vasculare is not so regularly defined or so rich as in the outer layer, and is much less so in the inner layer. A perimysium elasticum is present in the external layer of the cervix. This arrangement whereby the main amount of elastic tissue is placed in the outer two layers of the uterus has the advantage that it does not interfere with the contraction of the vessels; besides, any two points in the periphery are further separated, on dilatation of the uterus, than two points near the center, so that this supply is adapted to subsequent demands. The arrangement whereby the elastic fibers are arranged at right angles to the muscle-fibers prevents any interference with contraction of the muscle and the vessels. The above-mentioned is the natural condition found between birth and the climacterium, namely, elastic fibers in the interstices of the muscle-bundles and the muscle-fibers.

In the first half of pregnancy, so long as the myometrium grows, the elastic fibers undergo hyperplasia. The same is true of the parauterine and periuterine elastic fibers. In the second half there is a diminution, probably relative, through stretching; possibly, however, there is an absolute diminution. This seems to be irrational in view of the future stretching to which the lower uterine segment is to be subjected during labor; but in pregnancy there is a huge increase in the elastic structures situated at the sides of the uterus and around the lower uterine segment, so that on subsequent dilatation there is no interference with the muscle fibers of the uterine wall. This vicarious growth of powerful para- and perimetritic elastic fibers, the course of the uterine fibers at right angles to the line of contraction of the muscle-bundles, the network of elastic and fibrous perimysium about the individual fibers, the equal distribution of the coarse and fine elastic fibers in the external wall of the uterus, are ideal conditions; yet this typical arrangement is somewhat lost in pregnancy and the vessels of the stratum vasculare show proliferation, in places, of the elastic fibers of the intima.

During the puerperium, however, there is a decidedly increased formation of elastics, and after labor their increase is permanent, hand in hand with an increase of the muscle fibers and a thickening of the vessels.

The typical arrangement of the elastic fibers is lost in pregnancy, at the climacterium and likewise in the presence of myomata and in chronic metritis. The fibers are thickened and increased in number, and we

might say that the typical arrangement is heightened, in chronic inflammations, in the first half of pregnancy and at the puerperium. The fibers are swollen through serous infiltration in pregnancy in the puerperium and in metritis exudativa. The fibers are degenerated in pus infiltrations. The fibers increase in thickness up to the age of 50. After 50 they lose their continuity and become brittle and irregular. In old age they form lumpy groups in which the individual elastic fibers are to be scarcely recognized, and form groups around the arteriosclerotic vessels which are likewise grouped together. The elastic fibers disappear from the interfascicular connective-tissue interstices, so that the circumvascular islands of elastic fibers lose all connection with each other.

It may with truth be said that the thinner the wall of the uterus and the more shrunken the cervix the larger is the amount of elastic fibers, so that in the senile uterus the elastic fibers of the corpus and cervix are increased. A like condition is found in castration atrophy, and in addition the walls of the vessels are thickened and the elastic fibers in the adventitia are increased in amount. In atrophía uteri there is then an increased supply of elastic fibers. This is not alone a local condition, but is part of a general increase, such as takes place in the kidney, liver, testicle, heart, spleen, etc., and is an attempt at compensation for the disturbed mechanical relations due to the loss of epithelial and muscular tissues. It is true then that the greater the atrophy the larger is the number of elastic elements, and that an increase of elastic elements is present in all atrophies of the uterus, whether natural, artificial, or as a result of disease. The elastic fibers in the arteriosclerotic vessel walls of the stratum vasculare are increased and, passing out into the myometrium, they substitute the muscle-bundles, which is of itself a proof that the adventitia is a source for their formation. We have therefore a hyperplasia of the connective tissue hand-in-hand with a gradual degeneration of the muscle-fibers at menopause and in climacterium præcox, so that a framework is formed in the uterine wall, in the meshes of which lie the degenerating muscle-cells, accompanied by an increase of the fibrous perimysium, especially in the external layers. The elastic elements are thickened and lumped, likewise in the pericellular and interfascicular spaces. The stratum submucosum has naturally few elastic fibers, and we have here an elastose of the bloodvessels. Therefore in atrophy we have a diminution of the muscle elements, an increased amount of fibrous connective tissue, and increased amount of elastic elements of poor quality. Even if the latter are not increased in amount they are thickened, brittle, and form polyp-like groups. The greater the hyaline and sclerotic changes in the vessel-walls the greater is the amount of the elastic elements. So much for the valuable investigations of Pick.

Pichevin and Petit curetted a 41-year-old multipara for continued uterine bleedings, with no improvement. While performing a second curettage the bleeding from the uterus was so profuse that it was necessary to extirpate it. Examination showed an increase in the number of vessels which showed very much thickened walls, especially in the middle layer of the uterus. The muscularis was found almost substituted by vessels.

Marchesi reported a case of a 32-year-old multipara who had aborted several times. For great bleedings abrasio was done, but the bleedings increased and an hysterectomy was performed. The uterus was found

to be increased in size, and its walls were filled with the gaping lumina of blood- and lymph-vessels. Towards the mucosa the bloodvessels were increased so that at this part the uterine stucture had the appearance of cavernous tissue. The adventitia of the arteries showed an increase of connective tissue, the intima was thickened and uneven. Marchesi observes the occurrence of bleedings which are not controlled by abrasio, and where the endometrium shows no great changes. The pathological condition is therefore a change in the vessels themselves. He quotes from the French literature 6 recent cases of this character showing no affection of the glands, of the interstitial tissue, or of the uterine parenchyma, but decided changes in the vessels of the mucous membrane and the muscularis.

Reinicke reported 4 cases, 2 of which suffered from uterine bleedings which could not be controlled, the other 2, in addition, showed, on examination of the scrapings, suspicious areas. In these cases, secale and ergotin were of no value, dilatation of the cervix and the application of liquor ferri brought only temporary relief, and extirpation was necessary. Examination showed that, with degeneration of the muscularis, the arteries became stiff tubes. All four cases showed a thickened media of the vessels and a growth of perivascular and intermuscular connective tissue. This condition is viewed as an arteriosclerosis.

Cholmogoroff reports 2 cases, where the severity of the bleedings endangered life. No new growths or decided changes of the endometrium were present, and curetting brought no relief. The first case, a 42-year old Xipara, had aborted six times. Her menstruation had become gradually stronger, returning every 3 weeks, and lasting 8 days, with a loss of much blood and many coagula. In the intervals fluor albus was present. Hydrastis and ergotin being of no avail, an abrasio was performed and showed no abnormal condition of the endometrium. After a bleeding which nothing could control, the uterus was extirpated. On section, the vessels of the wall gaped. The mucosa was normal, the small vessels showed the intima to be thickened in spots, and almost obliterated. The muscularis showed an increase in the number of vessels, but this was possibly an illusion due to their twisted course. All the vessel walls were thickened with a diminution of the lumen. The connective tissue was increased.

The second case was a patient, 31 years old, who had aborted twice. Her menstruation lasted 8 to 10 days, and was very profuse, recurring every 3 and, later, every 2 weeks. Leukorrhea was also present. An abrasio showed a normal mucous membrane with hemorrhagic areas. The bleedings recurred so often, and were so profuse that an extirpation uteri was performed. The muscularis was firm and grated on incision. The vessels looked like pale strips on the cut surface, and their lumina gaped. The connective tissue was increased. There was a thickening of the arterial walls in the muscularis, especially of the media and the intima. There was an increase in the connective tissue, *especially that seeming to come from the adventitia of the vessels.*

We have, therefore, a very clear picture of the pathological changes and several distinct conditions which make a diagnosis positive. When menstruation becomes severe, menorrhagia, or metrorrhagia, and no local changes in the endometrium can be observed with a sound or with the examining finger, we may take it for granted that the following conditions are present: (1) Degenerating muscle-fibers poor in contractile power;

(2) an increased amount of fibrous connective tissue; (3) an increased amount of elastic fibers thickened and brittle; (4) arteriosclerotic vessels. Age is no criterion, since these changes may occur long before the natural climacteric period. If ergotin, stypticin, etc., are of no avail; if no decided changes in the adnexa, sufficient to warrant their being considered the cause of the hemorrhage be present; if an abrasio shows no altered condition of the endometrium; and if, above all, an abrasio does not control the hemorrhage, then the diagnosis of arteriosclerosis must be made. It is scarcely necessary to mention that myomata, sarcomata, and other local conditions are to be excluded on examination. What is the best method of treatment in these cases?

Among the cases reported by Dührssen are the following: A 37-year-old bleeder, decidedly weakened by profuse and long menstruations, and referred for hysterectomy, was atmokaused for 2 minutes. Nine days later a tubular membrane consisting of the entire mucous lining and the adjoining muscular layer was expelled. Twenty days after the first vaporization a second was performed lasting $1\frac{1}{2}$ minutes. There resulted an atrophy of the uterus $\frac{1}{4}$ cm. above the external os.

Another patient suffered for 4 years with almost daily hemorrhages and was curetted four times and treated locally without result. Gradual expulsion of the mucous membrane occurred after atmokausis. In the next three months normal menstruation occurred twice; then atrophy of the uterus and obliteration cavi as in case one.

In a third case treated in the same manner an obliteration cavi likewise resulted, in all probability, for amenorrhea was present 6 months. A fourth patient menstruated profusely for 4 years as the result of the presence of an interstitial myoma, the size of an apple. Curetting brought only temporary benefit. Because of a decided bleeding lasting 25 days, she was vaporized for 1 minute. Bleeding ceased at once. The next menstruation occurred after 9 weeks, lasting only 1 day. Decided diminution in the size of the uterus and its cavity was observed.

Pincus mentioned, among his first cases, a patient suffering from climacteric hemorrhages. The uterus was diffusely fibromatous. Large dose of stypticin, tamponade of the uterus and curettage were without effect. After vaporizing one minute, at a temperature of 105° C., bleeding stopped. Fluor lasted 12 days. Even after a period of 11 weeks there was no return of bleeding. His results in the treatment of post-climacteric fluor were excellent, since an obliteration of the uterine lining resulted. In 18 cases of climacteric bleedings from the uterus, treated by this method, 13 showed permanent benefit, evidenced by a cessation of bleeding lasting in the various cases at the time of writing from 2 years to 5 months. In 5 cases the period of observation was not sufficiently long to decide whether the cessation was permanent. In 2 cases the procedure was repeated after 8 to 11 weeks. In 3 of his own cases, which had been advised to undergo a total extirpation, obliteration was obtained by this method, and this result was frequently obtained in other cases reported to him, so that Pincus believes an extirpation uteri to be no longer a necessity in these cases.

Czempin reported a case vaporized by other hands. The patient, 27 years old, menstruated for the first time after labor after $4\frac{1}{2}$ months. The menstruation lasted

8 weeks. Atmokausis stopped the bleeding at once. Menstruation, however, did not recur and the patient suffered from symptoms of climacterium præcox. The uterus was found to be small and hard, the cervix was obliterated by cicatricial adhesions.

V. Weiss atmokaused at 100° C. for $\frac{3}{4}$ of a minute a 19-year-old nullipara who menstruated profusely for 8 to 12 days, sometimes twice a month. Examined after 4 weeks, the uterus lining was insensitive, a sound was easily passed. Later, no menstruation occurred and the patient suffered with headache and bleedings from the nose. Several months later the uterus was found to be small, hard and shrunken; the cervix was closed by cicatrices and a sound could not be passed. Two months later a protrusion at the external os was seen and was cut with scissors. Only the cervix was then passable for the sound, a distance of 3 cm. The body of the uterus was flat and shrunken.

It is to be understood that I have mentioned the cases of Czempin and v. Weiss not as instances of arteriosclerosis, nor simply as an evidence of the value of this method in these two individual case. I have included them in this portion of the paper to show what the effects of atmokausis may be, and the fact that the sad results above mentioned were due to this method speaks by no means against it, for, on the other hand, they have served to define the limit of time for an atmokausis where no obliteration cavi is desired. It should be known that vaporization is used for a large number of gynecological affections, in addition to uterine bleedings due to endometrial changes, and to climacteric local processes. Pincus and others use this method in quite an extended class of cases. For ordinary use the duration of vaporization is 10 to 30 seconds; for obliteration, 2 minutes or more at a temperature of 100 to 110° C. Pincus finds as indications for this method the following forms of affection: Endometritis, especially hemorrhagic and gonorrheal, incipient puerperal endometritis, uterine atony, bleeding due to interstitial myoma, subinvolution, as a preliminary to hysterectomy, as a palliative in inoperable carcinoma, in putrid abortion. To this treatment of the last mentioned affection decided objection has been raised on many sides. In addition, the method is used by Pincus very frequently in the treatment of climacteric bleedings and senile catarrh, in both of which cases an obliteration of the uterine cavity is desired. He finds the contraindications to be malignant growths of the uterus, tumor conditions of the tubes, and adnex abscesses.

The limits and absolute indications for this method are not yet defined. The generally accepted indications are those followed by Fehling, who has obtained good results in bleedings due to endometrial changes, and in climacteric bleedings. On the fourth to sixth day after curettage he atmokaused for five to twenty seconds at a temperature of 110 – 115° C. As said before, we used this method in the clinic Dührssen generally for uterine bleedings, not controlled by the curette and by local treatment. That excellent results are obtained, and that an obliteration of the uterine cavity is not its only value, may be seen from the following cases treated by atmokausis: A newly married patient suffering from gonorrheal endometritis became pregnant five months after vaporization by Dührssen, giving birth to a child later at full term. In this case, metal catheters being then in use, a beginning cervical stenosis, resulting from direct contact of the heated catheter, was overcome by dilatation. The second case was a 34-year-old

IVpara, who later aborted twice. After the last abortion two menstrual periods were accompanied by a decided loss of blood. After curettage, the next menstruation was normal, but recurred later at intervals of 23 days, the menorrhagia lasting six days. Vaporization lasting one-half minute was followed for a few days by a decided serous, yellow fluor, perfectly odorless. After regular menstruation for three months, it disappeared for three months, when its place was taken by a brown discharge which returned for four consecutive months. Examination showed the patient to be in good condition with a uterus the size of a fist, evidencing in addition Hegar's sign. Diagnosis, gravidity. Three weeks later she aborted. In these two cases atmokausis stopped the bleeding when local treatment and curettage failed. The normal character of the regenerated mucous membrane was evidenced subsequently, by the history of the cases and subsequent pregnancy.

The procedure in treating patients with this method is as follows: A positive diagnosis of the condition at hand must be made in all cases. Dilatation of the cervix is an all-important preliminary for many reasons. It permits of the examination of the uterine cavity with the finger. If no local changes are present, and if there is no retention of fetal membranes, not infrequently vaporization suffices without previous curettage. Retained membranes and malignant changes must be excluded before using this method. Only the finger can prove absolutely that the uterus is empty, and only curettage aided by examination with the finger makes it certain that we have removed those portions of the endometrium which are abnormal, and which are to be examined for malignant changes. In addition, dilatation of the cervix changes the three-cornered uterus into a circular canal so that subsequent use of steam affects all parts of its lining equally. In addition, dilatation of the cervix permits of the use of a large uterine tube, so that when the metal catheter, through which the steam passes, is introduced there is sufficient room in the uterine tube for the exit of the liquefied steam, and coagulated blood and serum. Lastly and equally important is the fact that a dilated cervix permits of a readier natural drainage of the uterus during the subsequent period. A necessary preliminary, then, not alone for the sake of a positive diagnosis, but for the other reasons mentioned, is dilatation of the cervix, for which, in all cases when feasible, laminaria are used. For performing vaporization narcosis is never necessary, since the uterus loses its sensitiveness on the contact of steam. It is only when this is applied to the cervix that some pain is experienced. As a rule, the cervix must not be treated, for atresia is possible before obliteration of the uterine canal, in those cases where obliteration is desired. If, however, the cervix be likewise vaporized, in such cases attention must be paid to the prevention of too early atresia. On the introduction of two Simon's specula, after disinfection of the vagina and cervix with lysol, the posterior lip of the cervix is grasped with volsellum forceps. The uterine tube, having been previously boiled, is then introduced in the cervix. This tube is marked so that it can be easily determined how far it has been introduced. If the entire uterine cavity is to be treated for only a few seconds, the uterine tube is introduced as far as the internal os. If the entire uterine cavity is to be treated for several minutes with the purpose of obliterating it, the uterine tube after previous measurement of the uterus with the sound is introduced to within

2 cm. of the fundus, the markings on the uterine tube permitting this to be done with exactness. The metal tube which carries the steam is then introduced, a bulb at its lower end closing the opening at the external end of the uterine tube. During the process of treatment this inner metal catheter is moved occasionally to permit the outflow of liquefied steam and coagulated blood, and to prevent too high pressure in the uterus. Shortly after contact of the steam the uterus contracts, and during the following minutes the uterine tube is slowly and gradually drawn out until, when it reaches the internal os, the entire inner surface of the uterus has been affected. If desired, the tube is drawn out up to the external os, whereby action on the lining of the cervix likewise takes place. The inner metal catheter does not extend fully up to the end of the uterine tube, so that at no time is it in contact with the uterus or cervix. The uterine tube being made of fiber stuff and transmitting no heat protects the cervix fully from contact with the heated metal inner tube. After treatment, rest in bed for 10 to 14 days is necessary; no irrigations being given except a vaginal irrigation after several days, if a large serous flow make the patient uncomfortable.

The duration of the application of steam is as a rule 15 to 20 seconds in younger women, where no obliteration is desired; 4 to 8 minutes if total obliteration be intended. The temperature used is 100° C. in the boiler of the instrument, which temperature is there registered by a thermometer. The boiler of the instrument is covered by a safety-valve which eliminates all danger, for the outlet tube is controlled by a stop-cock for two purposes. Firstly, it may be desired to use steam of a higher temperature which can readily be obtained if the stop-cock be closed. Secondly, before introducing the metal catheter, conveying the steam into the uterine tube, the stop-cock is opened to see if the steam appears and to remove from the metal catheter any water. The stop-cock is then closed for a second or two until the catheter is introduced into the uterine tube. At any time, if desired, the supply of steam may thereby be shut off.

It has been found experimentally that the steam when it enters the uterus is probably of a temperature of about 70° C., if the thermometer in the boiler registers 100°. Whether this be true or not, continued practice with this apparatus has shown that the above-named limits are absolute. There is generally a serous discharge for days or weeks after this treatment. The action upon the uterus and its lining may be judged by the character of the necrotic tissue which is thrown off in bits, or as a whole. This necrotic tissue makes its appearance in from 6 to 10 days if the action has been superficial, and in 10 or more days if a deeper cauterization has resulted. If this method is to be repeated, it should be done only after a lapse of 4 weeks, when the mucous lining has been regenerated. Not infrequently after this treatment, irregular bleedings or one or two increased menstrual bleedings may occur. The former are the result of the throwing off of necrotic tissue, the latter gradually go over into natural menstruation. The action of this method in causing involution may be seen from the fact that in a case of metritis chronica, with a uterine cavity 12 cm. in length, six months after vaporization the uterine cavity measured 6 cm. This patient had been curetted twice, had been treated with local application of iodine, and with numerous internal remedies. The contraindications

to the use of this method in cases not demanding operation for other conditions are malignant changes of the endometrium, and the presence of retained placenta or membranes. Other contraindications are those affections of the tubes, and those inflammatory conditions which are generally recognized as contraindications to curettage. While the value of atmokausis in other conditions is still a question of personal experience, there is no doubt that uterine bleedings, especially the bleedings of climacterium, and the uncontrollable hemorrhages occurring at this period, and in earlier years, are positive indications for its use, especially when curettage and other local methods are of no avail. Since our experience and the investigations mentioned above have proven the larger proportion of such cases to be due to local degenerative changes, we may say that atmokausis, if not a specific, is at least the best method of treatment for uterine arteriosclerosis.

THE COEXISTENCE OF CARCINOMA AND FIBROMA IN THE CORPUS UTERI.¹

BY W. A. NEWMAN DORLAND, A.M., M.D.
of Philadelphia.

Associate in Gynecology, Philadelphia Polyclinic; Assistant Obstetrician to the Hospital of the University of Pennsylvania, etc.

I.—THE FREQUENCY OF UTERINE FIBROMA.

Two years ago I had the honor of reading before this society a paper on the modern methods of treatment of fibroma of the uterus, which, as you know, is one of the commonest pathologic conditions of woman-kind, and one of divers clinical aspect. Thus, according to the investigations of Champneys⁶ based upon the records of St. Bartholomew's Hospital, of all the patients seen in the Department for Diseases of Women from January, 1866, to July 13, 1899—a little over 40,000 women—together with almost 6,000 patients admitted to the wards of that hospital, from 3 to 15% of these cases showed the presence of uterine fibroids in varying degrees of development. Pozzi claims that one-fifth of all women who arrive at the age of 35 are so afflicted, while Klob states that 40% of the uteri of females who die after the fiftieth year contain fibroid tumors. Bayle asserts that 20% of all women over 35 years of age present uterine fibroids, while Winckle in 575 autopsies upon females found only 12% fibromatous. Of 135 women dead under 35 years of age examined by Martin only 5% had fibroids. Senn claims that marriage increases the frequency of the disease, and that in 33% of the married women the tumors cause sterility. According to Twombly⁷ another set of statistics show that these growths occur in the unmarried 25% and in the married 75%, and that 30% of the married remain sterile. As you will note from the foregoing statistics my original assertion that this is one of the commonest afflictions of womankind may be amply verified.

II.—CANCEROUS DEGENERATION OF FIBROID TUMOR OF THE UTERUS.

To-night I shall present to you one of the rarer manifestation of the diseases—a form of degeneration

¹ Read before the Barton Cooke Hirst Obstetrical Society of the University of Pennsylvania, February 20, 1901, and the Judson Daand Society of the University of Pennsylvania, March 18, 1901.

which, it is claimed by many writers in gynecology, fibroid tumor has never been conclusively demonstrated to have undergone. I refer to carcinomatous changes in the fibroid tumor itself and in the corporeal endometrium—a condition quite distinct from carcinoma of the cervix of a fibromatous uterus. The association of carcinoma of the cervix with uterine fibroids is of comparatively frequent occurrence, and will not receive extensive consideration at this time. It is now very generally admitted by scientific investigators that the combination of malignant and benign tumors in the uterus is quite possible, Roger Williams⁴¹ stating that fibroids coexist with uterine cancer at some point in that organ in 9% of necropsies, and that uterine fibroma and cancer of other localities coexist to the extent of 18.5%, while Chiari⁶ claimed that uterine fibroma predisposed to the development of carcinoma either in that organ or elsewhere. Williams and others, however, reject this statement as unfounded in fact. Carcinomatous degeneration of a fibromyoma, on the contrary, is quite a rare occurrence.

Last summer I performed a hysterectomy upon a patient primarily for the relief of carcinoma of the fundus uteri, the diagnosis having been made from a microscopic examination of scrapings removed two weeks before the major operation. The uterus at the time of the abdominal section was found to be infiltrated with small, nodular, fibromatous growths, one of which, submucous in situation and projecting well into the uterine cavity, had become involved in a cancerous process. I present the result of the pathologic examination of the specimen which was made by Drs. Kirkbride and Deal, of the Polyclinic Hospital. A pathetic incident associated with this report is, that it was probably the last examination ever made by Dr. Kirkbride, who succumbed shortly afterwards to an attack of typhoid fever. Drs. Kirkbride and Deal write as follows:

Microscopic examination shows the uterus fairly normal in shape with the presence of numerous fibroids in its walls. It measures 15x14x13 cm. in diameter, and is of very firm consistence. The external surface is studded here and there with small, round, firm masses. The cut-surface shows the uterine cavity to be of fairly normal size, and the uterine walls are thickened from the presence of numerous fibroids. The internal surface of the uterus is studded with small fibroid nodules and three millimeters from the line of the cervical incision is a thickening of the endometrium, of oval shape, measuring 10x6 mm., and elevated 2 mm. above the surface of the surrounding tissue. Extending into the uterine cavity are two small fibroids and a polyp measuring 2½x1½ cm. in diameter. In the upper right cornua of the uterus is seen a sloughing mass, measuring 4x4 cm., evidently a degenerating fibroid nodule. This area is quite necrotic, and from it a yellowish-white semifluid juice can be expressed. Cutting into the fibroid one encounters some calcification. The microscopic examination gives the following results:

Slide 1.—A section taken from the thickening 3 mm. above the cervical incision, stained in hematoxylin-eosin, shows the tissue to be composed mainly of muscular fibers, with the presence of the uterine mucosa on its internal surface. The mucosa measures 2½ mm. in its greatest width, and decreases at one end until nothing but the muscular coat is seen. The glands, where present, show but little of their normal arrangement,

and in these places they are somewhat dilated and show proliferation of their lining epithelium. Elsewhere the whole mucosa has been replaced by a mass of large-sized epithelial cells, with large, oval, pale-staining nuclei, which arrange themselves atypically in relation to themselves and the surrounding connective-tissue stroma. Many of the nuclei show karyokinetic figures, and there is very little, if any, intercellular substance. There is a marked infiltration of small, round cells, with a few polymorphonuclear leukocytes. Blood-vessels are fairly abundant, and hemorrhagic areas are seen in the mucosa between the cells. Some distance beneath the mucosa, one sees in the muscle-tissue small nests of these large epithelial cells separated from one another by bands of normal muscle-tissue. The whole muscular wall is markedly infiltrated with small, round leukocytes. *Diagnosis*—Glandular carcinoma.

Slide 2.—A section of the uterine polyp stained in hematoxylin-eosin shows a great proliferation of the glandular elements of the uterus within a fairly loose edematous connective-tissue stroma. These glands show dilatation of the lumen and some proliferation of their lining epithelium, and in many places the lumen is completely filled with a homogeneous mucoid material which is stained blue with the hematoxylin. The proliferation is apparently confined to the glands, and shows no tendency to invade the surrounding tissue. The stroma shows some infiltration of leukocytes, and the bloodvessels are fairly abundant, with here and there small hemorrhages into the surrounding tissue. *Diagnosis*—Glandular polyp.

Slide 3.—A section taken from the degenerated fibroid nodule, stained in hematoxylin-eosin, shows the presence of large bundles of connective tissue interlacing with one another. There is a round-cell infiltration, and the bloodvessels are only fairly abundant; no hemorrhages are present. The bundles are made up of connective-tissue fibrils with spindle cells which contain elongated nuclei. The surface shows the same carcinomatous degeneration as noted in the first slide. *Diagnosis*—Fibroid polyp with carcinomatous degeneration of its surface.

The foregoing report confirms the diagnosis as made at the time of the hysterectomy of malignant degeneration of a fibroid tumor of the uterus.

III.—THE LITERATURE OF CANCEROUS DEGENERATION OF UTERINE FIBROIDS.

Reference to the literature of this extremely interesting subject establishes the fact that the opinions of gynecologic surgeons and pathologists still largely vary as to the possibility of the association of the malignant with the benign growth in the uterine tissues above the cervix. Thus, Champneys⁶ remarks that "malignant degeneration, though often talked of, is seen very rarely indeed. Its chief sign would be rapid growth." He has never seen a case in which a well-marked fibroid has taken a malignant growth. Franklin H. Martin²⁹ likewise says: "I have had an opportunity of examining and having under observation for long periods an unusually large number of fibroid tumors of the uterus, and I have never known one to undergo carcinomatous degeneration. Fibroid tumors do not predispose to carcinomatous degeneration. Cancerous change may occur, however, in a fibroid uterus as a coincidental disease, but in no way as a direct result of the fibroid."

Harrison¹⁶ remarks that degeneration of a fibroid into sarcoma has been observed, and even rarely into carci-

noma, while Palmer³² states that "the weight of opinion is that fibroids do not become malignant, although malignant growths may be associated."

Wallace,³³ in speaking of the degenerative changes to which fibroid tumors are subject, gives their order of frequency as follows: "Fatty (the most frequent), myxomatous and cystic (the next frequent), the sarcomatous (which probably existed from the beginning), and the calcareous—the rarest of all if we except the carcinomatous," which he has never met.

Ashton⁸ states that "fibroid tumors may be the seat of cancerous or sarcomatous degeneration. Whether or not a fibroma can become a malignant tumor is as yet undecided. It is a clinical fact, however, that these degenerations are frequently observed associated with fibroid tumors of the uterus." Homans,¹⁷ on the other hand, admits that the fibroid tumor may develop a cancerous character, while Goffe¹⁵ remarks that "carcinomatous and sarcomatous degenerations have been attributed to fibroid tumors, but this is still a disputed point."

According to Madden,²⁸ the theory of Sir James Simpson, which was subsequently adopted by Professor Klebs, was that while fibroid tumors have nothing carcinomatous in their nature, nor any tendency to undergo malignant degeneration, they may secondarily become the seat of carcinomatous deposits, or, as Klebs expresses it, with the hyperplastic new-formations (the fibromata) heteroplastic new-formations become associated, within which myxomatous and sarcomatous developments occur.

A. P. Clarke⁷ writes that "the record of cases coming in my own practice shows unmistakably that the malignant degenerative changes to which these growths are prone are not of rare occurrence;" while C. P. Noble,³⁶ in the discussion of Clarke's paper, remarks that "we may find carcinomatous changes after fibroids, but I have not seen a carcinomatous change in the tumor itself." He believes such a change is extremely rare. He has seen a number of cases of carcinoma of the cervix as a complication of fibroid in the uterus.

Twombly³⁷ positively asserts that the transformation of intrauterine myomata into carcinoma has never been demonstrated, while Anderson¹ diametrically states that carcinomatous or sarcomatous degeneration may take place in a fibroid or in the uterine tissue adjacent. In one case which he saw there was a new-formation of a cancer, or a degeneration of the tumor itself, which seemed to have been the result of the frequent irritation produced by puncturing the parts with an electric needle. He also remarks² that Martin, of Berlin, as quoted by Irish,¹⁸ in 205 cases of extirpation of myomatous uteri, found 9 cases which showed carcinomatous, and 6 cases sarcomatous, degeneration. Leopold claims that fibromata may become fibrosarcomata, and in one of his cases he observed a carcinomatous formation within the myoma. Ehrendorfer¹⁰ held that the mucosa of a fibroid uterus may become carcinomatous. D. Tod Gilliam¹⁴ says that he has never attended a patient whose death could be traced to malignant degeneration of the growth. He has removed several uterine fibroids that gave strong evidence of malignant degeneration, but these were rare as compared with the number of cases in which no such indications existed.

Lockhart³⁶ admits the possibility of carcinomatous degeneration, especially when the tumor is of large size and the patient is near the menopause. On the other

hand, De Boncaud⁹ denies the occurrence of cancerous degeneration of uterine fibroids, and affirms that the simultaneous development of both neoplasms in the same uterus is purely accidental, while H. Macnaughton Jones²¹ states that carcinoma of a fibroid uterus is a much rarer complication than sarcoma. Ford¹¹ remarks that a very practical question arises as to whether myoma does not occasionally become cancerous. The answer of the pathologist, he admits, is that it may become carcinomatous. Landau,²² in criticising the reasons generally advanced in favor of treating fibroid tumors symptomatically, states that though a myoma is usually a benign tumor it does not necessarily remain so. Apart from the possibility of its breaking down and sloughing, metaplastic processes—sarcomatous or carcinomatous degeneration—are not uncommon, and death from metastasis has been known to occur, though the tumor was, histologically, a simple myoma. This malignant degeneration is especially apt to occur at the climacteric period, or after that time in cases in which the menopause has been postponed owing to the presence of the fibromyomatous growth.

Oliver³¹ writes as follows: "There has been of late some discussion in the medical journals as to the association and relation of fibrous tumors of the womb and cancer. It is maintained by some physicians that under certain circumstances a fibroma of the uterus may take on malignant action. The denial of such a possibility is just as stoutly made. I have a faint recollection that I have seen this transformation occur, but I hesitate to express myself absolutely on this matter." Finally, Cullen,⁸ in his recent admirable work on "Cancer of the Uterus," states, "in spite of a rigid search I have failed to find among our own cases a single instance in which an adenomyoma has become carcinomatous." He has found, however, two instances in which a pure myoma had become invaded by the disease. Such, in short, is the more recent expression of opinion of eminent gynecologists at home and abroad, as to the possibility of the suprainplantation of a malignant upon a benign growth in the uterine wall.

IV.—THE HISTOLOGY AND PATHOLOGY OF UTERINE FIBROMATA AND MYOMATA.

A brief study of the microscopic features of uterine fibromyomata will explain the great rarity of this form of malignant degeneration of such neoplasms, and the evident reluctance of the scientific gynecologists to admit the possibility of such a change. As Madden²⁸ has clearly indicated, uterine tumors are at the outset almost entirely myomatous in nature, but sooner or later in most cases they become modified by the increasing development of the connective-tissue sheaths of the muscular fibers, so that more or less of a fibrous nature is superimposed on the original tumor. Klebs pointed out that during this process of transformation into a fibrous growth the lymph-spaces and bloodvessels within the tumor are obliterated in part, and the line of demarkation between the individual muscle-fibers becomes indistinct or even totally lost. In the small minority of the cases the original tumor retains its myomatous tissue, appearing as a growth composed of smooth muscular fibers of a greyish red transparent color and evidently contractile in nature. In either case epithelial formations are completely wanting and the development of a carcinoma is, histologically, impossible. On the contrary, the development of myxomatous and sarcomatous degenerations would be

expected to occur if the tumor malignantly degenerated at all, and clinical experience has amply demonstrated this to be the usual, though rare, form of malignant degeneration of uterine fibroids, the process proceeding from the neighborhood of the bloodvessels, and invading only the muscular tissue, which undergoes a speedy proliferation with the production of a rapidly-growing one-sided malignant tumor.

As to the nature of the muscular tissue from which the uterine myoma develops, the theories are again at variance. Can they develop from the mature muscular fibers of the adult womb? Senn maintains that they cannot, while Winckle inclines to the belief that they do not come from muscle-tissue at all, but that they spring from the uterine interparietal bloodvessels, and Klebs from the connective tissue of the bloodvessels. Velpeau's theory that they develop from small clots in the uterine walls has been disproved by Pozzi, and Kleinwächter's belief in their origin in a round-cell formation along the course of the capillaries has not been substantiated. There seems to be much reason in the arguments advanced by Anderson¹ that these fibroid tumors are localized or diffuse hypertrophies of embryonic (mesoblastic) uterine parenchymatous tissue, and composed, therefore, of unstriped muscular fibers.

Whichever of the foregoing theories we may be inclined to accept as the most plausible, it remains true that from their histologic formation carcinomatous degeneration would seem to be an impossible occurrence. How, then, are the undoubted cases of this rare complication that have been recorded to be explained? Madden²⁸ claims that genuine carcinomata can only proceed out of fibromyomata in cases in which the formation of the tumor extends to the surface of the mucous membrane; secondary extension of the carcinoma into a myoma may then happen in the same way as into the normal uterine muscular tissue from the endometrium, either continuously or discontinuously.

Such seems to have been attempted in one of the cases reported by Babcock⁴ from the clinical service of Dr. Noble, of this city, in which the capsule only of the fibromyoma had been invaded by an epitheliomatous growth originating in the cervix. Roger Williams,⁴¹ in his most admirable paper on "The Question of the Origin of Malignant from Nonmalignant Uterine Neoplasms," claims that in cases of this kind the cancerous disease usually spreads from the mucosa to the fibroid by the way of the perivascular lymphatics, and goes on to say that "in like manner uterine fibroids projecting into the abdomen sometimes become cancerous through extension of the disease from adherent neighboring organs, as the ovary, intestine, and omentum." Kümmel²⁴ records a case of secondary cancerous involvement of a subperitoneal fibroid, the primary disease originating in an adherent ovary. "A number of instances have been recorded," Williams proceeds to state, "of fibroids projecting into the uterine cavity and bearing on their surface a cancerous growth or ulcer." Examples of this kind have been reported by Schramm³⁴ and Ehrendorfer¹⁰ in corporeal polyps, while Frank,¹² Wahrendorff,³³ and J. Williams³⁹ have recorded instances in which the polyp was attached to the cervix.

A second method, not so common as the foregoing, by which a uterine fibroid tumor may become the seat of secondary cancerous degeneration is by metastatic dissemination of the malignant disease from a primary focus at some remote portion of the body. An incident

of this rare accident is recorded by Schopter,³⁵ the patient suffering from a primary cancer of the lung, a uterine fibroma ultimately presenting a secondary nodule of the disease.

Finally, the rarest method of all by which a fibroid tumor may become the seat of malignant changes is by primary involvement of the tumor itself. Roger Williams⁴¹ claims that hitherto only about a dozen instances of this occurrence have been recorded, and in most of these the evidence is far from being thoroughly convincing.

He reports an undoubted case of this rare condition. As a primary carcinomatous change would seem to indicate the presence of epithelial tissue, some other explanation than already given must be sought in order to understand this phenomenon. Fortunately, in 1896 new light was thrown upon the matter by the paper of von Recklinghausen, who observed in addition to the ordinary fibromas, myomas, and fibromyomas of the uterus, certain muscle-tumors in which glands and cysts were present.

These neoplasms he termed "organoid myomas," and he then stated his belief that the epithelium of these glands and cysts was derived from parental inclusion of fragments of the Wolffian bodies within the tissues of the coalescing tubes of Müller, or from cut-off postfetal outshoots of epithelium, growing from the uterine mucosa deep into the muscularis. Landau,²⁴ in commenting on this statement of von Recklinghausen, recalls "that the tubes of Müller are so situated in the embryo that the upper segment of each tube lies laterally to the Wolffian body of the same side; also that at a lower point, which corresponds to the tubo-uterine junction of postfetal life, the tube of Müller crosses the Wolffian duct, coursing in a median ventral direction, and that the lowest or vaginal section lies median to the duct of the Wolffian body." These relations being borne in mind, it is not difficult to understand how fetal inclusion of epithelium from the Wolffian ducts within the muscularis uteri or in the inner extremity of the Fallopian tube could be accomplished.

A strong confirmation of von Recklinghausen's theory, as pointed out by Landau, is the fact that these adenomyomas are very frequently bilaterally symmetric, and are much more common in the peripheral layers of the uterine muscularis near the tubo-uterine junction. An additional confirmation is to be found in the striking similarity in the epithelial tissue of the Wolffian ducts and the gland tubules of the adenomyomata.

On the other hand, this theory of von Recklinghausen is combated by investigators of equal ability and powers of observation. Thus, Lockstaedt²⁷ describes seven specimens of fibromyoma in which he found follicles or cysts lined with epithelium. The tumors were nearly all subserous and were attached in the neighborhood of the Fallopian tube, so that it seemed to him more plausible to infer that the epithelial elements were derived from the glands in the tubal mucosa, rather than from remains of the Wolffian body, as inferred by von Recklinghausen. He also opposes Orlof's view that the tumor may grow around and include epithelial pouches. Legnen²⁵ calls attention to the fact that the epithelial cells which are sometimes found between the muscular fibers and in the meshes of the connective tissue in fibromyomata are more common in those which are adjacent to the endometrium. These

cells usually appear as single, irregular layers lining blind follicles. He believes that they are derived by proliferation of the glands of the uterine mucosa. Ivanoff's¹⁹ inaugural thesis upon this subject is based upon an examination of 77 fibromyomata of the uterus, the majority of which were of the subserous variety. He was able to find glandular elements in only a single case, hence he concludes that uterine adenomyoma is very rare. He does not believe that embryonic remains which have been present for many years in the uterus can suddenly develop into a fibromuscular neoplasm. In the specimen he examined a zone of irritation was present around the epithelial tubes and cystic cavities, as shown by dilatation of the vessels and round-cell infiltration, the same as in cases of localized obstruction of the circulation.

These two distinct theories as to the origin of cancer of a uterine fibroid therefore exist, and must claim consideration. However, what the source of the glands and glandular tissue may be, it remains evident that it is in this tissue and in this tissue only that primary cancerous changes of fibroid tumors must originate.

We conclude, therefore, from the foregoing study of the clinical and histologic manifestations of reported cases, that it is possible for fibroma and carcinoma of the uterus to coexist, and that this coexistence may manifest itself in one of three distinct ways as follows, given in their order of frequency: 1. Fibromyoma of the corpus uteri with carcinoma of the cervix, the increased vascularity of the uterus and the irritant leukorrheal discharges attendant upon the benign tumor favoring in those women so predisposed the development of cervical malignancy. 2. Fibromyoma of the corpus uteri with associated adenocarcinoma of the endometrium, the malignant disease not invading the benign tumor, but originating either in the tubular utricular glands or in the included glandular vestiges which may be present. 3. True cancerous degeneration of an adenomyoma, the malignant change originating in glandular vestiges, included in the uterine growth, or the carcinomatous disease invading the benign growth by extension from an endometrial adenocarcinoma through contiguity of tissue.

V.—TABULATED CASES.

I append a series of authentic cases collected from literature in which the fibroid tumor itself was invaded by the cancerous growth either primarily or secondarily, as proved by careful macroscopic and microscopic examination. They are as follows:

1. Schramm,²⁴ a cancerous involvement of an intrauterine fibroid polyp.
2. Ehrendorfer,¹⁰ a cancerous involvement of an intrauterine fibroid polyp.
3. Frank,²⁵ a cancerous degeneration of a cervical fibroid polyp projecting into the vagina.
4. Wahrendorff,²⁶ a cancerous degeneration of a cervical fibroid polyp projecting into the vagina.
5. John Williams,²⁷ a case of fibromyomatous polypus projecting into the vagina, and bearing on its surface a squamous-celled cancerous ulcer, processes of which had invaded the substance of the fibroid.
6. Jessett,²⁸ a case of fibromyoma of the uterus taking on malignant action; palsy of rectum; recovery.
7. Kümmel,²² a secondary cancerous degeneration of an intraabdominal uterine polyp by extension from cancer of the ovary.
8. Schöpter,²³ a case of metastatic involvement of a uterine fibroid from a primary cancer of the lung.
9. W. Roger Williams,⁴¹ a case of intramural fibromyoma infiltrated with colloid cancer, occurring in a single woman, 43 years of age.

10, 11, 12, 13. Klob, Glaeser, Liebmann, and Coe, reported by Seuer,³⁵ each a case of cancer originating in uterine fibroids without primary involvement elsewhere.

14. Thorn,³⁶ a case of cancerous degeneration of an intrauterine fibroid.

15. Babcock,⁴ a case of squamous epithelioma of the cervix uteri in which the disease had invaded the capsule of a fibromyoma.

16, 17, 18, 19. Geuer,¹³ four cases of primary cancerous degeneration of a myoma.

20. Dorland, the case reported above.

SHOCK IN ABDOMINAL OPERATIONS.*

By FENTON B. TURCK, M.D.,

THE use of the term "shock" usually demands an apology. In the absence of knowledge of the pathology of this complex symptom we recognize only the phenomena, the effects of certain changes that seem to occur through the medium of the nervous mechanism. The study of the innumerable ways we may excite this remarkable phenomenon "shock" has added much to our knowledge both from a scientific and practical standpoint. The distinction made between shock and collapse (loss of the fluid of the blood) is valuable as a classification, but brings us no nearer to a knowledge of the pathology.

The recent work of Crile (Cartwright Lectures, New York, 1897) adds much to the value of the older observers on the methods of inducing shock, and the effects upon blood-pressure, respiration, etc.

Boise's conclusions (Transactions, Amer. Association of Obstetricians and Gynecologists, 1898) on the theory of hyperirritation of the sympathetic system, instead of a paresis of the nerves governing the heart, circulation, respiration, etc., are in accordance with many recognized facts, and have been alluded to by other observers.

* Presented before the Pan-American Medical Congress, Havana, 1901.

In recognizing the nervous phenomena we are still shrouded in mystery, and while each observer may add something of value to our present knowledge, we must admit that the pathology remains obscure.

I have reported many observations and experiments on this interesting subject, and the results seem to indicate two important factors not investigated sufficiently by other experimenters. One is the decreased resistance against infection when shock is present. The second is increased resistance against infection, produced by the internal application of heat while preventing shock, or reducing shock when present. Especially is this most marked when the heat is applied within the colon, stomach, or within the abdominal cavity, the two latter locations being the most effectual. No such marked effect was produced when the heat was applied to the skin. In these experiments it was shown that even virulent staphylococci and streptococci would not develop when inoculated into the peritoneal cavity of animals (dogs, guineapigs, rabbits), providing the heat stimulation continued for one hour. On the other hand, if the viscera were exposed to the air for a certain length of time, and shock thus produced, even what we term nonpathogenic microorganisms introduced into the abdominal cavity rapidly develop, resulting in death of the animal.

It will thus be seen that one of the important factors in shock is a lessened resistance to infection, while an increased resistance is obtained in the reduction of the shock by the application of heat to the splanchnic area.

I have shown by my own experiments and those of other observers, that the skin of the abdomen is a source of infection. It was shown that these germs cannot be removed even by our most painstaking aseptic procedures. That the microorganisms found are in a measure "nonpathogenic," but if the vitality is reduced by shock or otherwise, these so-called non-pathogenic microorganisms may produce infection and death. To prevent these germs from gaining access to or infecting the abdominal cavity, I described a method of covering the abdomen with an "artificial skin" or thin rubber dam sheet that is made to adhere fast to the skin; hence, I designated the method by the appropriate name, "artificial skin." (*New York Medical Record*, August 11, 1900, p. 208). I have also had rubber sheets made, with an opening already formed, to fit closely to the body and securely fastened so that the same sheet may be used over again. For practical purposes, the artificial skin which I previously described is more simple, as all that is necessary is to take a piece of this rubber dam and cement it to the skin like a surgeon's adhesive plaster. I have used various cements; simple bisulphide of carbon will dissolve the rubber and cause a sheet of rubber to adhere to the skin. I have had several special cements made for the purpose. A thin rubber cement is useful. I have tried a cement made of galvanum. Rubber and balsam, when sterilized, forms a firm adhesive sterile plaster to fix the rubber to the skin. It can be easily removed.

When the artificial skin is thus cemented over the skin of the abdomen or any other operation area, it forms a perfect protection from infection and lessens the danger of shock that may result partly from the evaporation of the wet skin.

The rubber protector may be cut to the size required. After this protective artificial skin has been made adherent to the real skin, it can be left to be opened by

the surgeon, the incision being made the same as if the rubber covering was not there.

The methods of preventing shock, or reducing it when present, have been previously described by the author. (Paper presented to the Thirteenth International Medical Congress, Paris, August 2-9, 1900; published in *Medical Record*, August 11, 1900, under the title, "The Care of Patients During Surgical Operations." Also, "Improved Methods and Details in the Care of Patients During Surgical Operations," *Journal of the American Medical Association*, June 9, 1900.) One method consists of introducing into the stomach a thin rubber bag attached to the author's double current stomach-tube, which is provided with an inlet and outlet tube. When in the stomach one side of the double tube is connected with an irrigator, and the water at a temperature of 50° C. (122° F.) is allowed to flow into the bag within the stomach. About 500 cc. is used and allowed to remain a few minutes, when the water is permitted to flow out through the outlet tube. Where it is desirable, a continuous flow is permitted, allowing 300 or 400 cc. of water to remain in the stomach throughout the treatment. Within 20 minutes this produces the profound effects previously shown by experiments on animals and numerous observations on patients, made by the author. If the temperature of the water introduced into the intragastric bag is gradually raised to 55° C. (131° F.), the highest physiologic action is obtained, and this is used, not only to prevent shock, but more especially to reduce profound shock when present.

The second method of preventing or reducing shock, previously described by the author, is that of the introduction of small and thin rubber hot-water bags covered with the flat gauze sponges into the abdominal cavity during operations for laparotomy. The temperature of the water in the bag is 48° C. These bags are partly filled with sterile water, tied, and kept in a hot-water receptacle at 48° C., ready for use. These heated flat sponge bags are not only useful in holding back the viscera from the operative field, but supply the necessary constant heat to prevent shock, and consequently, as I have previously shown, prevent the infection that results from the lowered resistance accompanying shock.

To determine the changes of the blood during shock, I injected the serum of animals in shock into healthy animals, and by increasing the dosage I found that animals so injected soon manifested the symptoms of shock. These experiments were repeated a sufficient number of times, and the results were constant in the disturbance of circulation, respiration, lowered temperature, resulting in collapse. Thirty animals were used, including guineapigs, rabbits, and dogs. The following experiment will illustrate:

Two dogs, brothers, 11 months old.

Dog No. 1. The abdomen was opened and the viscera exposed to a cool draught of air; at the same time the viscera were frequently manipulated until profound shock was produced. Loss of reflexes, lowered blood-pressure, failing respiration, temperature reduced to 95° F., marked congestion of the splanchnic vessels and marked anemia of the periphery. Time, one hour and 55 minutes. The animal was then bled and the serum used to inject into Dog No. 2. Injection of 5 cc. produced but little noticeable effect. When 50 cc. had been used the animal showed marked fatigue. When 150 cc. was injected the animal was in a state of collapse.

The blood from the animal in shock was injected into two guineapigs, injection being made subcutaneously into the back of one animal and into the abdominal cavity of the other. One lived 8 hours and the other 12, but both died from shock. These two experiments were controlled by animals injected with water and with blood from an animal not suffering from shock; neither of the controls showed any symptoms of shock.

Rabbits and guineapigs are far more susceptible to the injection of serum from an animal in shock than a larger animal. A rabbit will sometimes go into convulsions and manifest all the evidences of suffering by snake poisoning. Small injections, frequently repeated, will establish the phenomena of shock without convulsions. I have also found that those animals thus injected are rendered more susceptible to infection, but this point requires more experimental work to establish it beyond a doubt. The conclusions are well shown that in shock there are tissue and blood changes that are produced, and when the serum of animals in shock is injected into a healthy animal, it produces shock in the second animal. This corresponds to Mosso's experiments on fatigue, in which fatigue was produced in one animal and the injection of the fatigued animal's blood into a healthy animal resulted in fatigue in the second animal.

In another series of experiments, I found that when an animal is stimulated by heat for one hour or more, the heat applied within the splanchnic area by methods previously described, immunity or resistance against infection was thus produced. When the serum of such an animal was injected into another animal, there was an increased resistance produced, or a partial immunity to infection. Animals so protected could not always be saved, but the death from infection was retarded sometimes for one or two weeks. These facts establish a most important point in the pathology of shock, namely, the alteration of the tissue-cells and blood in shock. The nerves seem to act here as a transmitter of impulses that result in these tissue changes that we call shock. The chemical changes in muscle contraction, with resulting fatigue, may illustrate the part that nerves play in fatigue, so in shock. The phenomena of shock are too complex to explain by a single theory, but we must regard it as connected closely with the phenomena of altered metabolism. When metabolism is more satisfactorily worked out we may more clearly understand the phenomena we call shock.

A PRACTICAL MODIFICATION OF THE PHENYLHYDRAZIN TEST FOR GLYCOSURIA.

By ROBERT N. WILLSON, M.D.,

of Philadelphia.

So MANY urinologists have found it easy to criticise and discard as too intricate or liable to error the so-called phenylhydrazin test for glucose in the urine, that I have been led to offer a suggestion that may bring it within the reach of even the least skilled experimenters. Before describing the modifications that render it both practical and expeditious, and, what is still more important, almost free from error, it may be well to give the main steps of the test as usually performed. These consist in boiling a certain quantity of the suspected urine (usually 50 to 100 cc.) in a beaker in a water

bath, after adding a small quantity of sodium acetate, and one-half as much phenylhydrazin hydrochlorid. Fischer and von Jaksch allow the above mixture to boil for half an hour, but use such a small quantity of urine (especially von Jaksch, who recommends 6 to 8 cc.) that their followers in imitating the method have frequently failed to demonstrate glucose, although shown by other tests as present in large quantities. Sahli advises 10 cc. of urine, to which two drops of a concentrated lead acetate solution have first been added, and the urine then carefully filtered to remove the albumin. He then renders the filtrate acid with a drop of acetic acid. I would say here that while the use of lead acetate solution and the subsequent filtration are measures conducive to a more cosmetically perfect test, the albumin in no way interferes with the execution of the method, and so far as concerns the final outcome need not be removed. This being true, and providing the urine is already acid, nothing need be added except the essential reagents, thus saving to the experimenter two steps in Sahli's method. Both von Jaksch and Sahli have suggested the use of a test-tube in the place of a beaker as a handy substitute for the more bulky glass dish that requires a large water bath. R. T. Williamson, in an excellent article on the phenylhydrazin method (*Manchester Med. Chron.*, 1899), suggested an even quicker plan for the preparation of the phenylhydrazin-urine solution, and yet the majority of observers have held to the water bath, and have at last become weary of the procedure and discarded the test altogether. Williamson makes a decided advance in modifying the old suggestion of Hoffman and Ultzman (*Atlas der Harnsedimente*, Wien, 1872), by heating equal parts of sodium acetate and phenylhydrazin hydrochlorid ($\frac{1}{2}$ inch of each in an ordinary test-tube) with the urine over a spirit lamp for two minutes after the solution has reached the boiling point. He then places the test-tube in the rack and leaves it there for from half an hour to twelve hours or more before examining. As he says the crystals are "frequently found after the tube has been standing half an hour, but after boiling the tube I have generally placed it in a test-stand and did not examine the deposit until next day, or at least until 6 or 8 hours afterwards." Thus, although he has rendered easy and speedy the first step in the method, even Williamson fails to furnish a test that will always react within a practically short space of time. If the phenylhydrazin test is to be of advantage it must be rendered prompt, and in the following suggestions I believe I can bring it decidedly within the reach of even the most exacting requirements.

Method I.—The test may be carried out according to Williamson's method up to the point at which he places the tube in the rack, after boiling for two minutes. At this stage, instead of allowing the solution to cool gradually in the tube, or to stand for hours, I have found it practicable to place a drop directly upon the slide and examine it under the low power (AA Zeiss) of the microscope. In from $\frac{1}{2}$ to 2 or 3 minutes depending upon the temperature of the room, and the quantity of sugar present, if the reagents have been thoroughly mixed and dissolved in the urine before boiling, typical crystals of phenylglucosazone can be seen forming beneath the eye of the observer. The character of these crystals can be readily seen from the accompanying figures. It need only be mentioned that the color is a brilliant yellow, contrasting strongly with the brown globules and dark yellow granules that often appear in the precipitate, and

especially when the urine is rich in uric acid or in urates.

Method II.—I prefer to the direct application of the flame to the test-tube, as rather more certain and slightly more sensitive, the use of a small beaker as an improvised water bath. I make it a rule to boil the solution in the test-tube in this bath, for 5 to 10 minutes over a Bunsen burner, and then to examine immediately as before, with a single drop on the slide, and with the low-power lens. The slightly slower heating insures a perfect solution of the reagents before boiling, and avoids a source of error that with this rapid method may prove of decided moment. This method requires but little longer, and the whole examination is complete within 10 or 12 minutes.

I have believed, since my first attempt and failure to demonstrate the presence of 5 % of glucose in a specimen of urine, that my error and that of a large number of observers lay in the use of a too small quantity of phenylhydrazin hydrochlorid, and at the same time of too little urine. Not more than a few weeks ago, while demonstrating the test to a class of medical men, a physician, himself a laboratory teacher, remarked to me that either "my phenylhydrazin was spoiled, or else

FIG. 1.—Phenylglucosazone crystals, as they appear when first forming in the drop of urine under the lens (DD Zeiss.)

the test was of no use." He had placed glucose in normal urine, tested as he thought properly for the crystals, and had obtained nothing but the customary normal flaking of the phenylhydrazin salt, and no crystals. In the first place I may say that very rarely, if ever, does the phenylhydrazin salt "spoil." In the second, the opportunity was too good to be lost. So, before the class, and with his own materials that had in his hands failed, I carried out what I have described as Method II. Within 10 minutes of the preparation of the first solution I had typical phenylglucosazone crystals in abundance, and forming fast under the lens of my microscope. Where the doctor had erred I do not know. Either the heating had been too hurried, the mixing had not been thorough, or his proportions of the salts used had been inaccurate or too meager. The eye soon learns the quantity necessary, and no measure is required. Until practice affords this accuracy, however, no more frequent source of error will be found than the lack of sufficient salt of one kind or the other. The directions that I have given, however, are exact, and if glucose is present the test as described will not fail to produce the crystals. The test-tube method is undoubtedly the practical one, with or without the water bath.

To the tube, half full of urine, I add one gram¹ (equivalent to the amount that will heap a silver quarter dollar piece) of sodium acetate and *as much* phenylhydrazin hydrochlorid. The amount of these reagents mentioned by Williamson, while vitiating the accuracy of the test in no way, is unnecessarily large, and as the phenylhydrazin salt is somewhat costly, its lavish use will prove somewhat of an item in the laboratory account.

If sugar is present in large quantities, large yellow

FIG. 2.—Final formation of crystals in ordinary (1-5 per centages of glycosuria (DD Zeiss.)

crystals will form in the field as the drop cools. The long slender spicules and the tendency to a rosette or cluster form, will differentiate the phenylglucosazone crystals from any others that may form from other substances. (Fig. 2.) In high percentages of glycosuria the formation of crystals is so profuse that there is no difficulty in their detection with the low-power lens. I prefer, however, to use no coverglass in the method, since in this fashion the urine cools both gradually and quickly, and presents a concentrated field for observation. Just here can occur a source of error. In the event of a minute quantity of glucose being present,

FIG. 3.—Final formation of crystals in very low percentages of glycosuria (DD Zeiss.)

minute crystals only may form that cannot be clearly seen with the low-power lens. These, however, can be easily recognized with the higher power (DD Zeiss) as characteristic though tiny crystals of the same nature as the larger ones. (Fig. 3.) By this method I have repeatedly discovered glucose in quantities far less than

¹ Attention has repeatedly been called by different authorities to the tendency of this salt to produce eczema of the skin. My personal experience has covered no such cases.

0.1% in the urine. Williamson claims accuracy for the test in the presence of 0.01% of sugar, and my experience tends rather to confirm than to doubt his statement. A comparison of the phenylhydrazin test with the ordinary tests for glycosuria can be made in the following recent experience. I was examining a specimen of urine sent to me for analysis in which I later demonstrated about 0.1% glucose in the evening specimen and a still more delicate quantity in that of the morning. In both specimens I obtained a negative reaction with Fehling's solution, although a few weeks previously the evening specimen had contained 5% of glucose. After standing between 5 and 10 minutes the Fehling test began to give a suspicious color-reaction, that never went beyond a yellowing of the blue, and gave no precipitate. I then instituted the phenylhydrazin test after the above method (II), boiling the solution 10 minutes; and in less than a minute after placing the drop on the slide saw tiny crystals of phenylglycosazone begin to form. These I could see, but barely distinguish with the AA lens. Fehling's test required 5 to 10 minutes to give a very doubtful reaction; the fermentation test would have required several hours, had it responded at all; while the phenylhydrazin method as I have described it was practically conclusive in less than a minute after the boiling was complete. Altogether the latter test requires under the most disadvantageous circumstances between 10 minutes and $\frac{1}{2}$ hour. In my own hands I can be confident of its success within a time limit of 10 minutes.

Of course the question arises here (1) as to the unvariableness of the appearance of the crystals when glucose is present; (2) whether other substances than glucose will produce with phenylhydrazin similar crystal formations; and (3) as to whether or not the test is so delicate as claimed by some, no matter how executed, as to cause the formation of crystals from the small quantity of glucose supposedly present in normal urine. In answer to the first point I will simply submit the instance already mentioned as one of a large number in which the phenylhydrazin test has been the only one apart from the clinical symptoms to conclusively demonstrate the presence of sugar. I have never met with an instance in which the customary tests (Fehling's, bismuth, fermentation) all agreed in reacting to the glucose and yet the phenylhydrazin test registered a negative decision. In regard to the second point I must answer that certain substances do at times form with phenylhydrazin hydrochlorid crystals similar to those of phenylglucosazone. Glycuronic acid or alkapton, (of which traces may be normally present in the urine, but never in quantity sufficient to give this reaction) may as a result of the ingestion of certain drugs² appear in quantity in the urine, and lead to the reduction of copper oxide in Fehling's test, bismuth, silver salts, and also to the formation of crystals somewhat similar in appearance to those under discussion. Usually they are smaller and the spicules are shorter and less rich in number. The occurrence of alkapton is, however, a rare one, and can be determined at once by its disappearance on discontinuance of the use of the drug.

Crystals should then no longer form with the phenylhydrazin salt. Alkapton fails to give the bismuth reaction (Nylander's solution), and does not ferment with yeast. Its crystals, moreover, melt at 114° to 115° C. Williamson mentions the fact that sodium salicylate and

salol may cause a like reaction, probably due again to glycuronic acid formation in the urine. Salkowski states also that the pentoses may form crystals. The pentoses are, however, rare forms of sugar, and as their crystals melt at 159° C., they also can be separated from those of phenylhydrazin which melt first at or about 205°. Levulose may also rarely form a crystalline sediment, but is again such a rare occurrence, except in company with glucose, that it hardly enters into consideration. Finally with regard to the oft-claimed oversensitiveness of the phenylhydrazin test, I can present an unbroken individual experience. I have tested many times what I believe to have been normal (glucose free) urine, and by all of the methods above mentioned, and have never obtained crystals that were in any way liable to be confused with those of the phenylhydrazin salt. Williamson quotes a series of 50 specimens of urine tested in the same way and with a like conclusion. In the same specimens he tested with the method of Moritz (boiling for one hour or more) and obtained crystals somewhat similar in appearance in many of the cases. Moritz's method seems undoubtedly oversensitive. On the other hand those facts appear to me to prove conclusively the value of the phenylhydrazin test when executed according to the above suggestions, which outline a procedure so much simpler than the one that is liable to error that the latter can be chosen only through ignorance or intention. I feel safe in recommending it as the most accurate, and at the same time one of the most expeditious of methods of examination for glucose in the urine. Certainly as a negative test it is unimpeachable, while as a positive indication of the presence of glucose in large or small quantities (0.01% +) I believe it shows so few sources of error as to make it preferable to any of the other resources at our command. Bismuth and copper react with uric acid, kreatinin, and other normal constituents of the urine, and often their reactions with glucose are obscured by the presence of albumin in one of its many forms. Phenylhydrazin hydrochlorid responds to none of these substances, nor does albumin interfere with its reaction. Even in the case of the polariscope is the latter recommendation in a measure wanting. In the presence of less than 0.1% glucose the much-relied-on fermentation fails, while phenylhydrazin has demonstrated so much smaller a quantity that it has suffered the accusation of such a delicacy as the demonstration of a possible normal amount. We have, therefore, in the modified phenylhydrazin test not only one that can be used with satisfaction by those skilled in laboratory methods, but one that is within the ability of the veriest tyro, or the humdrum doctor of the oldest school, provided he has advanced to the use of a microscope and test tube. For accurate work I would suggest the routine use of three tests—phenylhydrazin, Fehling's, and fermentation (the latter always done with a control test of glucose-free urine). The polariscope, when within the means of the worker, forms a valuable adjunct. Rubner's test with lead acetate and ammonia is also an excellent one. But for practical results, I believe of all these the modified phenylhydrazin test combines the most valuable qualities and assures the greatest accuracy. Permanent specimens of the crystals may be mounted directly in balsam after drying upon the cover glass or slide.

Awarded Golden Crown.—Professor Grassi has been awarded the distinction of the Golden Crown by the Society of Italian Agriculturists, in recognition of the valuable services rendered by him in the investigation of malaria.

² Among these are opium and its alkaloids, curare, camphor, chloroform, chloral, etc.

HOW TO PREVENT STAMMERING.*

By G. HUDSON MAKUEN, M.D.,

of Philadelphia.

Professor of Defects of Speech at the Philadelphia Polyclinic.

THE old adage, "An ounce of prevention is worth a pound of cure," was never more applicable than it is in the consideration of the treatment of stammering. The time to cure stammering is before it begins. Few, if any, children stammer from the very outset. Speech is an acquired faculty and stammering is an acquired defect. The tendency to stammer is inherited in many cases, and children having ancestors who stammered should be very carefully guarded. The inherited tendency consists in a transmitted defective nervous organization, the exact character of which has not yet been differentiated.

So complex are the mechanisms of speech that the wonder is that we do not all stammer. In no other faculty of the human organization is so great precision of coordinate muscle-action required, and not only must there be a perfect coordination between the numerous muscles, but there must also be a perfect harmony and coordination of action between the mechanisms themselves. Indeed, it is the lack of this latter coordination that causes stammering in the great majority of cases.

The three mechanisms of speech are the respiratory, the vocal and the oral mechanisms, and there are few stammerers who cannot employ any one of these mechanisms separately. They can breathe, they can vocalize and they can articulate, but they have trouble when they attempt to do these three things at the same time. In other words, they are unable to coordinate the action of the three mechanisms of speech.

The first act of the child on coming into the world is to breathe. This breathing is instinctive, automatic and involuntary. Its function is to aerate the blood and it is therefore necessary to life. Its physiology is well-known, and it differs very materially from the physiology of the breathing employed in the production of speech. This latter breathing incidentally performs the function of the former during the speech-processes, but its own and chief function is to supply the vocal organs with a column of breath which, in turn, becomes voice, the material out of which speech is made. In other words, while the breathing of speech production incidentally aerates the blood, its chief function is to produce voice.

The management of the breath for speaking and singing is an art and it should be taught in the schools. Its physiology, I explained several years ago in a paper entitled, "Artistic Breathing," presented before the American Laryngological Association, and published in the PHILADELPHIA MEDICAL JOURNAL. Good vocalization is also an art, and, although it is the product of a separate and distinct mechanism, it should be studied in connection with breathing.

I have defined voice elsewhere as being a moving column of breath set in vibration by its own impact with the vocal bands and reinforced by its diffusion through the various resonant chambers into the surrounding atmosphere. The production of voice, therefore, requires not only a precise coordinate action of the muscles of each of the two mechanisms, the respiratory and the vocal, but it also requires a precise coordinate action of the mechanisms themselves, and defects of vo-

calization are often due to a lack of this harmony of coordinate action.

The vocal element of speech depends for its perfection upon the moving column of breath, upon its density, its rate of motion, and its accurate control by means of the respiratory muscles. One child will stammer because the column of breath is not sufficiently dense; another because it moves too rapidly or too slowly; and another because it moves in the wrong direction, the attempt to vocalize being made on the inspiratory effort. There is a faulty action of the respiratory muscles and a lack of coordination between the respiratory and vocal mechanisms which necessarily result in a faulty production of voice. And it is here that the trouble with many stammerers exists. Voice, the material out of which speech is made, is not forthcoming at the exact time at which it is required for purposes of articulation into syllables and words, and there is, therefore, a lack of coordination also between the vocal and the oral mechanisms.

An apt illustration of the relation between these two mechanisms is given by Dr. Wyllie in his book on "Disorders of Speech," in which he likens the vocal mechanism to the bow hand, and the oral mechanism to the string hand of the violinist. Just as the most precise harmony of action must exist between the two hands of the violinist, so must there be perfect harmony of action between the vocal and oral mechanisms of speech. If you imagine for a moment a failure on the part of the bow hand to perform its functions and an effort on the part of the string hand, not only to do its own work, but also, at the same time, to supply the deficiency of the bow hand, you will have a good illustration of what takes place in the case of the stammerer. The vocal mechanism is defective in its action. It may be lacking in promptitude, as it is in many instances, and the oral mechanism tries to articulate something that does not exist, and the result is necessarily a failure. The word will not come out and the first impulse is toward greater effort. This greater effort generally takes place in the acting mechanism and results in an overflow of nerve-energy into this mechanism and sometimes into other portions of the muscular system and gives rise, not only to the grimaces of the stammerer, but also to the spasmodic contortions of the muscles sometimes observed in other portions of the body.

The proximate cause of stammering, therefore, is a faulty coordination of the three mechanisms of speech, viz., the respiratory, the vocal, and the oral. This faulty coordination in turn is generally due to a faulty action of one of these mechanisms which always results in a faulty action of them all.

The trouble does not often appear first in the oral mechanism, where the muscle-spasms, characteristic of the stammerer, are so manifest, but rather in the respiratory and vocal mechanisms, and the spasms of the articulating muscles, as I have shown above, are due to the overflow of nerve-energy into these parts.

Having considered the immediate causes of this affliction, let us now look for the more remote, or first cause. What is it that causes the faulty coordination of the muscles and the mechanisms of speech? This we naturally look for in that portion of the nervous system supplying these muscles and mechanisms. It may exist in any portion of the nerve-tracts running from the peripheral organs of speech to the centers in the cerebral cortex. In the majority of cases, however, it is probably in the motor speech-centers of the bulbous

* Read before the Third Pan-American Medical Congress in Havana, Cuba.

portion of the spinal cord. It is not a gross anatomical lesion; that is to say, one that may be differentiated by any methods at our command; but that it is a structural condition, differing, however, slightly from the normal, is quite probable, and I am looking forward to the time when a more minute study of the pathology of the nervous system may enable us to demonstrate it.

The fact that this peculiarity of the nervous system is transmitted according to the laws of heredity, tends to suggest and confirm the above theory. If stammering were the result of a mere functional derangement of the nervous system, heredity would not figure so conspicuously as a contributory cause. There is something more definite than we have yet discovered, which is handed from one generation to another, and which predisposes those possessing it to this distressing affliction. Children who acquire the habit of stammering, whatever may be the exciting cause, generally have within their own nervous organizations the germs of the disease. Hence it is that they should have the most careful management during the period of the development of speech. Prophylactic measures should be instituted before the stammering actually begins. In the majority of cases these measures should be wholly educational. The little patients merely require to be taught how to think calmly and connectedly and how to speak, and this is not a difficult thing to do.

Stammering is not generally of sudden onset, but it is of slow development and begins during a period of great excitement. A child attempts to describe some little incident that may have happened during his play hour and which seems to him of overwhelming importance. He is anxious to make his description as vivid as possible and he thinks there is no time to lose. In his haste, various details of the incident become confused in his mind and he has difficulty in selecting the proper words and in enunciating them as rapidly as appears to him to be fitting to the occasion. His excitement, moreover, increases his heart's action and his breathing and they become wholly inadequate to the requirements of normal speech. The result is a repetition of the initial sound or syllable of some word that may be uppermost in his mind. This is what is known as stuttering. It is a prodrome of stammering; and it is at this stage that the treatment should begin.

What not to do is quite as important as what to do, and therefore, it may be well to begin with a few "don'ts." In the first place don't scold the child. He is already in an excited condition and scolding will merely add fuel to the flame. Don't make fun of him or call his attention to his defect or use the word stammering or stuttering in his presence, for all this will embarrass him and lead to a nervous dread of future trouble of a similar kind. Don't allow him to associate with stammerers or even to hear another stammer, for unconscious imitation is an important causal factor at this stage of the affliction.

Always keep in mind the fact that the child begins to stutter because he has not yet learned to combine the art of ideation with that of oral expression. His thoughts come rapidly and in confusion and the words with which he attempts to clothe them tumble out spasmodically, somewhat as water comes out of a bottle. He tries to say everything at once. He cannot arrange his thoughts in order and he has difficulty in selecting suitable words for their expression. The vocal and articulating organs share in the general confusion and

they soon begin to lose their normal automatic action. An effort is made to control them by will power and this usually results in failure. These organs cannot be forced into proper action.

Inasmuch, therefore, as the trouble often arises in a faulty mental action, the first indication is to direct the mental processes into normal channels. We must disentangle the somewhat twisted thoughts and to do this the attention of the patient should be unconsciously diverted from the all-absorbing subject at hand until he has regained his mental equilibrium and then he should be led gradually back to the main subject and given a clear conception of exactly what it is that he desires to say and shown how to say it in a deliberate and clear manner. It is quite possible to do this, and careful direction and management at the very inception of the trouble will almost surely prevent the formation of the stammering habit. It is after the habit has been formed that the difficulty in curing stammering arises. The treatment then is not only more difficult, but it is much more complicated because of the many new factors entering into the problem.

Children never should be allowed to stammer and the habit never should be formed. It is quite probable that the above treatment, if properly carried out during the prodromal period, would result in completely stamping out this dreaded disease.

BELL'S PALSY ASSOCIATED WITH COMPLETE ANESTHESIA IN THE TERRITORY OF THE FIFTH NERVE.¹

By JAMES HENDRIE LLOYD, A.M., M.D.,

of Philadelphia.

Physician to the Methodist Episcopal Hospital and to the Home for Crippled Children; Consulting Neurologist to the State Hospital for the Chronic Insane at Wernersville, Pa., and to the Pennsylvania Training School for Feeble-Minded Children at Newry.

INVOLVEMENT of sensation in a minor degree is not uncommon in ordinary cases of peripheral paralysis of the seventh nerve. This implication of the fifth nerve in such cases is, however, merely shown, as a rule, by pain in and around the point of exit of the seventh nerve from the skull. This pain is usually not severe and not long continued. On the other hand, a true anesthesia in ordinary Bell's palsy is very rare, and even when present is usually but limited in extent and quite evanescent. In my own observation of peripheral paralysis of the seventh nerve, of the ordinary type due to cold, and known as Bell's palsy, I have never seen until now a well-marked anesthesia. I have, of course, seen a conjoint paralysis of the fifth and seventh nerves, due to a gross lesion, such as a tumor, within the cranium, but of such cases I am not speaking here.

There is apparently very little recorded about anesthesia or other involvement of the fifth nerve in cases of Bell's palsy. The reason must be that such involvement is rare. Erb regards it as remarkable, considering the intimate association that exists between the fibers of the fifth nerve and those of the pes anserinus, that sensibility is not oftener involved, and regards this exemption as proof that in ordinary facial paralysis the inflammation is usually higher up in the trunk of the facial. Gowers says he has seen a few cases of diminished sensibility on the cheek,

¹ Read before the Philadelphia Neurological Society, October, 1900.

but his explanation that this is due to diminished sensibility of the nucleus of the fifth nerve due to the diminution of the number of muscular impressions, is quite unsatisfactory. Mills says that occasionally one or more branches of the trifacial may be involved in Bell's palsy, and this is due to a spread of the inflammation by contiguous structures. Eulenberg and others have recorded the occurrence of herpes zoster in cases of paralysis of the seventh nerve, but in such cases I should suspect a deep-seated lesion probably acting as an irritant to the Gasserian ganglion. Notta, in 1860, described a form of neuralgic Bell's palsy in which the first symptom was pain in the suboccipital and auriculotemporal nerves, followed after a period of eight days by the facial paralysis. But in this affection there was no anesthesia. The affection was a most anomalous one and suggests a resemblance to ophthalmic migraine, in which paralysis of the ocular muscles follows a severe bout of pain in the ophthalmic division of the fifth nerve. It was certainly not like an ordinary Bell's palsy, and I have never seen any record of other cases like it.

Webber, of Boston, wrote a paper on pain (not anesthesia) in Bell's palsy. He suggests, somewhat as Mills has done, that a "rheumatoid" inflammation of the trunk of the fifth nerve might occur at the points of exit of the nerve from the skull, just as occurs in the case of the seventh nerve. But in such an affection, I should think anesthesia would be present as well as pain. The occurrence of pain in Bell's palsy is, in fact, not difficult to understand; it may readily be caused by the swelling of the trunk of the seventh and consequent involvement of the small fibers of the fifth with which the trunk of the seventh is doubtless supplied. But the problem of a complete anesthesia in these cases is a far different one.

I have to present this evening a case of peripheral paralysis of the seventh nerve associated with complete anesthesia in the whole territory of the fifth nerve.

The clinical notes of the case, as taken by Dr. Cohen, resident physician, are as follows:

A. W., female, aged 20 years, has a negative family and personal history. The patient says she has always been nervous, but gives no history of hysterical crises prior to onset of present illness. No specific history is attainable, and there is no evidence of specific infection. On Monday, July 8, 1900, the patient slept in a draft. On Tuesday she had pain—occipital, frontal and on the vertex. She was dizzy and nauseated, but there was no emesis. On Friday morning the patient felt nauseated. Suddenly, while conversing, she felt her mouth draw to the left and she could not see out of her right eye. There was lateral flexion of the head to the right, and deafness in the right ear. Violent headache was present. The patient says she fainted. There was marked epiphora from the right eye. The patient grew worse on Saturday and Sunday. Her mouth became more distorted, the left angle being situated about half way between the ear and its normal position. She was admitted to the hospital on July 21.

Physical Examination—Dull mentally. Pain severe in right ear and down the right side of the neck, over the mastoid process, temporal region, and ramus of the inferior maxilla. Eyes: Sight poor, especially of right eye. Pupils: Uneven, right larger than left, dead to light and accommodation, movement of eyeballs good in all directions, orthophoria, no ocular palsies, conjunctival reflex absent in the right eye—also corneal. Eye grounds: No gross lesion, form field roughly taken under cover. Right eye contracted to fixation point; left eye markedly limited, but no central scotoma. Fifth nerve: Motor branches uninvolved. Patient cannot open mouth to full extent on account of pain; the temporal, masseter, and pterygoid muscles act perfectly.

Sensory branches: Complete anesthesia of the right side of the head, neck, and face, including the buccal surface (see Figure). Tactile, temperature, pain, and muscular senses absent over large area on right side of the head, neck, face and mouth. The special senses: Taste absent on the right side of tongue. Smell absent in the right nostril. Hearing diminished on the right side. Ear (right), membrane thickened; light spot slightly broken; pain on pressure over posterior auricular nerve. Seventh nerve: All branches involved; right side of face expressionless; lagophthalmus; escape of saliva from mouth; the faradic contractility of the affected muscles is almost completely abolished. Eleventh, spinal accessory: Contraction of the muscles on the right side; chin deflected to the left; pharyngeal reflex absent. Tongue protruded with difficulty, but not deflected from median line. No other part of the body is paralyzed; kneejerks sluggish; sensation elsewhere normal; some difficulty in urination—tendency to retention. Heart and lungs normal. Abdomen normal.

Abstract from Clinical Notes.—Since admission to the hospital the patient has had 4 distinctly hysterical crises characterized by weeping, globus, varying degrees of anesthesia of trunk and upper extremities, aphonia, muscular twitchings, semiconscious state, partial anesthesia of left, or sound, side of the face, and dropping of the lower jaw. There was no relaxation of the sphincters. These additional anesthetics have been temporary, passing off in a day or so. The anesthesia of the right side of the head, face, buccal surface and neck has remained constant. The patient steadily improved and regained considerable facial control. She could nearly

Anesthesia complicating a case of Bell's palsy.

close the right eye at the end of two months. There has been a gradual increase in response to the faradic current. At the end of three months the patient's condition was as follows: She still presented the above-described sensory disturbances, viz., abolition of tactile, pain, temperature, and muscular senses over a large area of the right side of the head, face, buccal surface and neck. Absence of the special senses of taste and smell on the right side. Considerable deafness in the right ear, diminished vision in the right eye. Contracted visual fields. Slight or partial reaction of degeneration. Electrical sense has gradually increased. At no time has there been any disturbance of speech apart from hysterical aphonia.

In seeking for an explanation of this involvement of the fifth nerve we have to consider several points. In the first place, the escape of the motor branch of the fifth seems to indicate that the lesion is not at any point within the cranium. It is difficult to see how a lesion at the base of the brain, involving both the seventh and fifth nerves, would allow the motor branch to escape, and also how the sixth nerve would escape. The intense pain at the beginning, with stiffness of the neck muscles, might suggest a meningitis, but the subsequent favorable progress of the case is against this theory. Besides, there has been no optic neuritis or other evidence of intracranial lesion. The case hardly presents the history or appearance of brain tumor. The involvement of taste is doubtless due to implication of

the chorda tympani, but the involvement of smell suggests an hysterical complication, and this leads to a consideration of the theory of hysteria.

Hysterical complications in organic nervous disease have been observed now so often by me that I have come to look upon them quite as matters of course. In the present case the evidence in favor of hysteria is both negative and positive. The negative evidence consists in the absence of any clear indication of an organic lesion to explain the anesthesia. The positive proof is briefly as follows: The association of the anesthesia with loss of the special senses, even sight, on the affected side. The loss of taste could, of course, be otherwise explained as due to involvement of the chorda tympani in the inflammation of the seventh nerve; it being now pretty well agreed upon that the chorda tympani and the intermediary nerve of Wrisberg are one and the same sensory nerve—called by Sapolini the thirteenth cranial nerve—and that this is the nerve of taste for the anterior half of the tongue. Favoring hysteria also are the hysterical crises, the fugitive anesthesia on the sound side of the face and elsewhere, the contracted visual fields, and the patient's occasional mental states. Rather against this theory, perhaps, is the permanency of the anesthesia on the affected side—nothing has served to dispel it. It has persisted now for three months, and is as obstinately fixed and as complete as an organic anesthesia.

Finally, in favor of hysteria is the fact that the anesthesia is not strictly limited to the territory of the fifth nerve. It overlaps this territory considerably except at the median line. As seen in the figure, the anesthesia extends down on the neck, below the territory of the fifth nerve, and back toward the occiput in the territories of the great and lesser occipital nerves and the auricularis magnus. It would be difficult to account for such an anesthesia by an organic lesion.

As to the paralysis of the seventh nerve, it is unquestionably due to an organic lesion—evidently a neuritis. The paralysis is not like an hysterical paralysis of the seventh in which blepharospasm is usually seen to take place of lagophthalmus. Besides, the reactions of degeneration are an unmistakable proof of its organic origin.

Black-Water Fever.—Ziemann (*Deutsche med. Woch.*, October 4, 1900) gives the following statements as the result of his experience in **black-water fever**. 1. In some regions severely affected with malaria there are found people who, after having had one or more attacks of malaria have a tendency to black-water fever which varies from time to time. As a rule the intensity increases with the number of attacks of malaria, but this is not always the case. It is not necessarily associated with a general hemorrhagic diathesis. 2. This disposition to black-water fever is seen chiefly in people who have been infected with the small parasites of the tropics, or with estivoautumnal fever, though ordinary tertian or quartan fever may produce it. 3. It is possible that there an especial virulence of the parasites is produced by local conditions, and that this leads to the hemoglobinuria. As a result of these observations he concludes that black-water fever may appear as a result of a new outbreak of malaria; it may be the result of a new outbreak of malaria with the coincident use of quinin; it may also appear in people who are predisposed thereto owing to earlier attacks of malaria by the mere use of quinin without any new attack of malaria. The latter cases are rare. Black-water fever has been observed in Togos negroes when they have never taken quinin. The same has been seen in other regions. It may be seen in very mild forms with only a slight brownish tinge of the urine. One case, which is worthy of attention, was observed by Ziemann. In this tropical malaria was

present. A dose of $\frac{1}{2}$ of a grain of quinin produced hemoglobinuria, and about $\frac{1}{3}$ this amount produced albuminuria. [D.L.E.]

Extra-genital Syphilis Transmitted to Several Members of the Family.—Tulinow (*Vratch*, Vol. 22, No. 2) related before the Pediatric Society of Moscow the following interesting cases: To the Hospital of St. O'ga were admitted a brother and sister, 5 years and 11 months respectively, both suffering from syphilitic affection of the buccal mucous membrane. From the history it was learned that the girl was infected by her brother through kissing, and he, in turn, was infected by a syphilitic janitor who occupied the same room. The little girl infected her mother who developed a hard chancre of the nipple. The father of these children also developed a hard chancre of the left tonsil. In the same hospital was received a boy 3 years old with a hard chancre of the lower lip. This boy infected two other children and his father and mother. At the same time the landlord's children, living in the same house, developed extra-genital syphilis. [A.R.]

Polyneuritis Due to Influenza.—Diemer (*Gaz. Heb. de Méd. et de Chirur.*, January 13, 1901, 48me Année, No. 4; Paris Thesis, 1900) refers to a case of **polyneuritis following influenza** that occurred in the service of Lépine. The nerves were examined histologically after death and the presence of parenchymatous neuritis was demonstrated and not interstitial neuritis. This complication of influenza ordinarily begins during the period of convalescence, like diphtheritic neuritis, to which it has often been compared. Motor troubles are constant in this condition, which is primarily a motor polyneuritis. The motor phenomena consist of paralyzes of so very variable location that it is impossible to assign to this form of polyneuritis a predilection for any particular group of muscles. It may be said that all the muscles may be paralyzed and that consequently the functional troubles that originate from the paralysis vary according to the localization of the lesions. Usually the paralysis is isolated either to the upper or the lower extremity with predominance on one side. Whatever their seat these paralyzes present common characters which, however, are not pathognomonic. Among the peculiarities of this form of paralysis are: 1. The predilection for the distal segment of the limb, which predilection diminishes in its intensity as the proximal segment is approached. 2. The extensor muscles are usually the ones that are involved. 3. The course of the affection is irregular. 4. The paralyzes are always flaccid. In addition to the paralytic phenomena ataxic symptoms are often observed which are due to the paralysis of the extensor muscles of the leg. Disorders of sensation are not very well marked in polyneuritis due to influenza, and they never attain the intensity observed in cases of polyneuritis due to alcohol. Atrophic and vasomotor phenomena are usually slight. Muscular atrophy was noted in nearly all cases. The psychic condition of the patient is not altered. The course of the disease may be acute or subacute; no case of chronic influenzal polyneuritis has been observed. The disease is nearly always cured without leaving traces of its existence, but in some instances incurable atrophies in certain groups of muscles have been noted. In the treatment of the condition the element of pain is the one most clamorous for relief. Absolute rest in bed is an essential in the treatment. If morphin is given its administration should be very short and it should never be used without first determining that cardiac lesions or involvement of vagus nerve are wanting. Antipyrin and sodium salicylate render great service. A very grateful application to the painful parts consists of circular bandages of linen wrung out of cold water which, in turn, should be covered with a layer of dry cotton, wool, and surrounded, finally, by a layer of impermeable tissue. When the disease is localized in the lower extremities prolonged refrigeration in the dorsolumbar region will be found of benefit. After the spontaneous suffering of the patient has disappeared; when the signs of the reaction of degeneration no longer exist, and when the examination of the nerves and the muscles shows a simple diminution of excitability of those organs, curative treatment should be instituted. In order that this treatment may be efficacious it should aim at the anatomic restoration as well as at the functional restoration of the altered muscles and nerves. [J.M.S.]

The Plague in San Francisco.—The truth on this subject seems likely to come to light in due time. Some of the exact facts are stated in the last number of the *Public Health Reports* issued by the Marine-Hospital Service, and are printed in our news columns today. The commission appointed by the Secretary of the Treasury was supposed to have made up its report and sent it in to the Secretary some weeks ago, but for reasons which doubtless seemed good to Mr. Gage this report was not promptly made public. We cannot too strongly protest against any further attempt to keep the plague situation in San Francisco a mystery. The local authorities in California have been guilty of suppressing the truth, and the United States Government should not tolerate this abuse any longer. Much less should it keep back any reports of commissions or government agents relating to this subject. The public is vitally interested, and all alike have an equal right to know the exact facts. It is unnecessary here to repeat the facts and figures given in another column. The announcement that 42 fatal cases of bubonic plague have occurred in San Francisco will be startling news to the vast majority of persons both within and without the profession. It heralds a serious situation, and it is a reproach to those public persons from San Francisco who were announced recently to have said in Washington that the only kind of plague existing on the Pacific Coast was of a "noncontagious" character. The general demand of the public—both lay and professional—ought to be for the United States Government to take the situation vigorously in hand, with the co-operation of the local government, if possible, but without that co-operation if need be. There is getting to be a sort of optimism about plague being easily controlled and eradicated—but the facts in India do not prove this, and at any rate we do not want to be driven to the proof of it by a widespread epidemic in this country.

Treatment of Malignant Tumors With Serum.—The discovery of a specific has long been the object of those engaged in studying the treatment of disease. Unfortunately, while belief in the existence of a specific for each morbid entity is reasonable, even as is the belief that there must be an antidote for every poison, the true specifics at our command are very few. Even in the cases of quinin we find cases of the disease for

which this drug is supposed to be a specific, in which it is devoid of action; and the same may be said of mercury. The specific action of antidiphtheritic serum has led investigators to turn their attention to serumtherapy as a means of solving the problem of obtaining a specific for diseases that, up to the present time, have been considered incurable. Some of the recent experiments in the line of curative serums have been made in connection with sarcoma. During 1899, Louis Dor (*Gazette Hebdomadaire de Médecine et de Chirurgie*, February 14, 1901) introduced a piece of a chondrosarcoma of the shoulder, about the size of an egg, into the peritoneal cavity of a rabbit. At first a large mass developed in the abdomen of the rabbit; but after about a year the mass was so reduced in size that only a small nucleus remained. Then a larger piece of a chondrosarcoma from a human subject was introduced into the peritoneum of the same rabbit. After this operation the fragment was absorbed in less than two months. This experiment seems to show that the serum of the rabbit may become cytolytic for certain sarcoma cells of man. In the next experiment a goat was operated upon. A bouillon was made from a melanotic sarcoma and injected subcutaneously. There was some reaction following the injection that lasted for about three days. Three months later the same goat received subcutaneously an entire melanotic sarcoma of the eye. The serum of the goat was then used in the treatment of two patients; one of whom presented general melanotic sarcoma of the lymph nodes of the axilla and neighboring regions with a presternal cutaneous tumor, and the other of whom was suffering from melanotic sarcoma of the leg. The first patient, twelve days after the institution of the treatment, had improved in general appearance and the tumors were smaller. In the second patient, after three weeks, during which about 100 ccm. of the serum were injected, the tumor was much modified in appearance. Reynier (*Gazette Hebdomadaire de Médecine et de Chirurgie*, February 21, 1901) has used a serum obtained by Wlaeff by inoculating birds with blastomycetes isolated from human carcinomatous tumors. The patient on whom this serum was used was suffering from an inoperable carcinoma of the tongue. The first injections of the serum were made July, 1900, and after ten injections the patient was able to resume his ordinary occupation. The lymph nodes in the neck remained large, however, and the tumor of

the tongue was still present in spite of the amelioration of the general condition of the patient. A second patient, who was suffering from a cylindrical epithelioma of the mammary gland, was much benefited after the administration of the serum, and the tumor appeared of the nature of a nonmalignant growth. Reynier admits that if the injections are stopped the disease will resume its course and the patient will finally succumb. Here, then, are two serums, both in the experimental stage. The first is produced by transplanting fragments of malignant tumor or by injecting a bouillon representing the entire tumor; the second, by inoculating blastomycetes obtained from malignant tumors. The great objection to the second method is that we are not sure that blastomycetes are the cause of carcinoma or of sarcoma. The first method would seem to stand more chance of success in the production of an anticarcinomatous or antisarcomatous serum, because, since the entire tumor is used, the pathogenic factor of the disease, whatever that may be, must surely be introduced into the animal operated on. It is not possible, however, at the present writing, to say that either of the serums advocated in the papers under review is a specific; because of the four patients treated not one was actually cured of his disease, and Reynier admits that the result of the administration of the bird's serum is merely palliative.

Some Timely Words About the Social Evil.—Dr. Prince A. Morrow, of New York, is a surgeon whose words carry weight with all men when he speaks on this wellnigh forbidden topic. He has both the personality and the professional experience, as well as the balanced judgment and fine ethical sense, which constitute him an excellent instructor for the people as well as for the profession on the delicate and extremely responsible question of the public recognition and control of the venereal diseases. In the present number of the JOURNAL Dr. Morrow presents a paper in which he traverses rapidly, fearlessly and completely this entire field. The author of the paper has no illusions, yet he is not pessimistic; while on the other hand he has scruples, but he is not puritanical. He sees in the social evil, as he aptly expresses it, a necessary evil, not in the sense that it is indispensable, but that it is inevitable. The drift of his paper is to make clear a few essential facts. Its worth consists in its not attempting to say too much. The regulation of prostitution is, at best, a dubious and imperfect way of controlling the propagation of the venereal poisons. In this country such regulation is practically impossible, because public opinion will not tolerate it. This was made clear in Missouri in 1871—and that State is the only one that has ever had the temerity to try to license prostitution. Sanitarians must reckon in this matter with public sentiment, whether they wish to or not, and in the meanwhile should not lose valuable time in vainly arguing this question from the standpoint of hygiene

versus morality. They should follow the course that Dr. Morrow points out, and try in some practical way to at least control and curtail the evil. That it can ever be entirely eradicated the history of mankind disproves; and while it is a fine thing to have enthusiasm in a good cause, it is somewhat Quixotic to believe that such a sordid and debauched curse as harlotry can ever be banished by the decrees of legislatures. The great merit of Dr. Morrow's paper is that it minimizes the purely ethical and sociological aspects of this subject, and treats it largely as a wise physician should, upon a purely pathological basis. His paper is fully up-to-date in the way it demonstrates the grounds for our enlarged views about the far-reaching effects of gonorrhea and syphilis, and his suggestions for meeting the evil are, we believe, about the only practical ones that can be devised. His arraignment of our hospitals for shutting their doors in the faces of venereal victims is timely and deserved, for their policy in this matter is worse than inhuman—it is short-sighted.

The Influence of Intemperance Upon the Death-Rate.—Whether alcohol be a food or a poison is a question that will be answered somewhat in accordance with the individual point of view. To the judicial mind it would appear—paradoxical as it may sound—that it may be either or neither or even both. The best disposition of alcohol is to place it—with its congeners, ether, chloroform, etc.,—in the category of drugs, with definite physiological and pathological activities, in accordance with the dosage employed, the frequency, mode and time of administration and the susceptibility of the individual who receives it. Like other agents and agencies capable of doing good, alcohol is—as might be expected—capable also of doing harm, and no one can appreciate better than the physician the evil results of alcoholic intoxication. These can be seen directly in various disorders of the digestive organs and in the more remote and widespread manifestation of arteriosclerosis and visceral fibrosis. In addition the impress of alcoholic excess can be observed upon the mortality-rate and there appears an intimate relation between alcoholic excess and vice and crime. Thus, in the United Kingdom, while the average mortality-rate has fallen from 22.5 to 17.2 per 1000 since 1872, the rate from alcoholic intemperance increased from 45 per million in 1875 to 77 per million in 1897. It is found also that the number of criminal offences is smaller in parts where alcoholic intemperance is less prevalent. Upon the physician as the conservator of the public health, therefore, it would seem incumbent to prevent and to correct so far as possible any tendency to alcoholic addiction, with the same earnestness as he strives to prevent and correct habituation to the use of chloral, cocaine, opium or any other substance prejudicial to health. A share of responsibility rests upon every physician in this matter.

The Business Outlook in Medical Practice.—The ratio of physicians to total population in the United States is rather more than 1 in 600. The 120,000 physicians are dying at the rate of about 25 to 1000. To make good the deficit of physicians by death, about 3,000 should be graduated annually. The population is also increasing at the rate of about 1,300,000 annually, and this increase could accommodate some 2,100 additional graduates in medicine annually. In 1899, according to statistics of the Bureau of Education, all of the medical schools of the country graduated not quite 5,000. Thus, statistically considered, there is a very slight favorable tendency toward the reduction of a tremendously overcrowded profession.

On the other hand, it should be remembered that as a country increases in density of population, it can support fewer physicians. For instance, European countries with a ratio of approximately 1 to 2000 of physicians to population, support their medical professions even more poorly than does the United States. Moreover, sanitary science and medical and surgical skill, as well as more wholesome modes of living, are markedly reducing the work of the profession. The well known fact that a fifth or sixth of graduates do not practise is little comfort, as this has always been the case, and it simply denotes the unfavorable conditions against which the medical man has to contend. Thus it is the urgent duty of every physician, by fair argument and reasonable means, to create a sentiment against the entrance of young men upon medical studies, unless they are especially fitted for their pursuit.

The Antitoxin Unit.—The antitoxin unit is defined as the amount of antitoxin which, when inoculated into a guineapig of 250 grams weight, will neutralize 100 times the minimum fatal dose of toxin of standard strength. Antitoxin may be present in varying amounts in the serum employed, and it is an important point to remember that the number of cubic centimeters of the serum injected is no index to the strength of the solution in antitoxin units. Until 1896 the definition of antitoxin unit above given was regarded as reliable, but in that year Ehrlich found that the same antitoxin is capable of neutralizing varying numbers of fatal doses of toxin according to the cultures used, and perhaps the method of preparing the toxin. For example, he found that the same amount of the same antitoxin might neutralize from less than 30 to 130 doses, according to the source of the toxin. A difficulty to be overcome was to maintain the standard strength of the toxin and antitoxin for testing purposes. Ehrlich prepared both toxins and antitoxins dried, in powder form, and kept them in vacuum tubes at a low temperature and protected from the light. The standard dilution of antitoxin which Ehrlich employs consists of equal parts of glycerin and 10% salt-solution. This mixture will maintain the strength of the antitoxin

dissolved in it for several months. The technique of the preparation of antitoxin was further modified by Ehrlich in that he mixed both the toxin and the antitoxin before injecting them into the guineapig instead of injecting them separately, as was at first practised. Ehrlich also employed the whole unit in the operation of standardizing instead of one-tenth unit, and the most important modification, that in place of making complete neutralization the end to be obtained, he shifted the end reaction to the death or survival of the guineapig used. For example, if we wish to standardize a certain toxin with the unit antitoxin we add to the antitoxin such excess of toxin that the resulting mixture will just prove fatal to a guineapig on the fourth day. By this procedure we have not only neutralized the antitoxin, but also added one minimum fatal dose. Theobald Smith for the past three years has employed Ehrlich's improved method, and with the test-serum obtained from Ehrlich has prepared all of the antitoxin for the Massachusetts State Board of Health. In the *Journal of the Boston Society of Medical Sciences*, Vol. 5, No. 1, he has presented a critical analysis of the combining power of antitoxins and toxins so prepared, and concludes that up to the present time Ehrlich's method is by all means the most satisfactory and accurate. It has been claimed by Park and Atkinson that if toxins are prepared in an absolutely uniform manner from the same cultures their neutralizing power is likely to be the same. Smith has demonstrated in a number of experiments that this may or may not be the case. The studies of Ehrlich and Madsen have revealed how intricate is the process of the neutralization phenomena, and up to the present time all hypotheses fail to explain them. Ehrlich has found that if he added to a definite quantity of toxin, different fractions of the antitoxin unit the results indicate that the neutralizing and the toxic power of the same toxin do not go hand in hand. Ehrlich (quoted by Smith) from his study of the various toxins infers from these results the presence in them of substances of different degrees of toxicity, as well as neutralizing power, towards antitoxins. He explains the multiplicity of variations which occur by the numerous combinations of these substances. Ehrlich has called these substances which appear in the fresh toxins, toxins and toxones. The latter have but little toxic power, but they neutralize antitoxin, and Ehrlich is inclined to look upon them as the feeble poisons which cause paralysis. According to their affinity to antitoxins he classifies the antitoxins present in any culture fluid into proto-, deuterio-, and trito-toxins. The proto-toxins have the strongest, the toxones the least affinity for antitoxins. These break up after a time into toxoids. Some of these secondary products are more stable than others. We are indebted to Dr. Smith for a convincing demonstration of the superiority of Ehrlich's method over others employed. The variable factors to be considered in the preparation of antitoxin

are: a uniform culture medium, the preservation of cultures so that deterioration may be minimized, and the effects of inoculations upon guineapigs. Smith has found a few animals out of the great number employed for experimental purposes who have withstood a single fatal dose without any local reaction whatever. He also mentions that the animals are apparently more susceptible in winter than in summer.

Must the Family Doctor Go?—Obliquity of view and extravagance of expression are among the venial sins of some of the modern newspapers. To deal in paradox is their specialty, and they exercise this privilege nowhere more rashly than on the subject of medical practice. For instance, one of our metropolitan dailies (by which expression we mean, of course, a New York newspaper), recently wrote a sort of obituary notice on the family doctor. On the authority of a fashionable specialist, this newspaper announced that the days of the general practitioner are numbered, and that in the near future the specialist and the trained nurse will monopolize the field. Even as it is, the functions of the family doctor, it thinks, can be performed just as well, if not a little better, by a well-trained nurse. Moreover, the specialist to occupy the field, will be the surgical specialist—the man who stands ever ready with knife in hand, because, according to our New York newspaper, the day is rapidly approaching when all, or nearly all, diseases will be cut out bodily. In this promised golden age, all that will be necessary will be for a well-trained nurse to recognize the disease and call in the surgical specialist, who will proceed to cut it out and hand over the patient again to the nurse, who will keep him aseptic and return him to business in due time.

All this sounds like persiflage, and was probably written by a man with his tongue in his cheek, but we take note of it because it represents superficially a kind of criticism that is growing too common. The family doctor is not doomed to extinction. Far from the day of his decline having come, the day of his greatest usefulness is only just beginning. It is evident, however, that he must, in one sense, be a specialist himself, *i. e.*, he must have special alertness of mind to recognize disease, and to know what remedy is needed. But the field of preventive and domestic medicine is largely his own, and will continue to be his. He will always occupy a position of great advantage, for he stands at the threshold. He will continue to dispense his patronage to the specialists, and they will know him when they see him. But he must be thoroughly trained for this work.

The Treatment of Varicocele.—Surgeon-General Sternberg has sent out from his office an interesting circular on the treatment of varicocele in which the experience of a number of army surgeons is given.

These observers all recommend the recently devised high operation, and since its employment they have had the most uniformly good results, particularly as regards the primary healing of the wound. As varicocele is considered a bar to enlistment and when occurring afterward a partial disability, the recruiting stations and the army furnish a large majority of the cases of varicocele which are operated upon. In civil life this condition is not looked upon as one of any moment unless, as is not infrequently the case, the patient has developed a distressingly hypochondriacal state of mind. It can be truly said that, excepting in applicants for the army and navy and for positions in some of our police and fire departments, operations for varicocele are seldom necessary. The circular concludes with some very wise remarks on the subject by Nicholas Senn. His observations regarding the usually innocent nature of this condition and the infrequent necessity for operation coincide with those expressed by William H. Bennett, in a recent lecture published in the London *Lancet*, March 2 (abstracted in PHILADELPHIA MEDICAL JOURNAL, March 23). Senn, in examining 9,815 recruits, found varicocele present in 2,078. One-half of these men were ignorant of the condition and only three or four acknowledged the slightest discomfort or pain. Undoubtedly it is true that the recruiting stations of the army and navy discover for most of these patients the presence of this condition, which Senn believes to exist in one out of every three or four males between the ages of 18 and 30 years. One point of difference in the operative technique of Mr. Bennett is that he urges the ligation of the spermatic artery with the veins, maintaining that the artery of the vas deferens and other small vessels from the tunica vaginalis are sufficient to supply the testis. He suggests that the fatty degeneration of the testis which sometimes follows the operation might possibly be due to an over-supply of blood without the proper means of its return.

One can but be pleased with the satisfactory reports found in the Surgeon-General's circular, but in the light of the experience of men like Bennett one must also conclude that many cases of varicocele are unnecessarily subjected to operation. In the absence of local and mental symptoms we are inclined to doubt the necessity for operation in civil life. In a soldier, particularly a cavalryman, it is somewhat different, as a large varicocele would certainly predispose to traumatism.

The Control of Marriage by the State.—The right of the State to regulate marriage has always been recognized in some form as a fundamental principle of law. Marriage, considered purely from the historical standpoint, is an artificial institution; that is to say, its very existence depends upon legal recognition. It is created by law, and in the eye of the law it is merely a contract of a special and peculiar kind. In the evolution of society the institution of marriage has passed

through several recognizable phases, but there has never been a time when it was not in some way or other the creature of the law. The culmination of this process of social evolution has been when marriage has come to be regarded in the canonical law of most races as a sacrament of the Church. But this is only a late phase of its development. Considering all these facts it is somewhat remarkable how really little the lawmakers of various nations and ages have interfered with the natural process of marriage. No civil institution, perhaps, has been less trammelled in its initial stage by the law—although the contract once made it has, as a rule, been jealously guarded. But the widest liberty in entering into the bonds of matrimony has, as a rule, been granted. Where restrictions have been imposed they have been usually for social, not for hygienic, reasons; as, for instance, when the marriage of slaves has been prohibited. But that natural prejudices, as well as the welfare of posterity, have also imposed restrictions is seen in the Levitical law against consanguineous marriage within certain limits, and in the interdiction by most countries of the marriage of lunatics and idiots.

There must be some reason why a contract so jealously guarded when once established, should be left so comparatively free from restrictions for almost all persons who choose to enter into it. The ancient Spartans, we believe, came the nearest of all really civilized nations to putting the entrance into marriage under the control of the State; in other words, to using marriage merely as a method for breeding healthy men and women. But Sparta was the least civilized of all the Greek States, and her example has never been followed. It has remained for the State of Minnesota to play this interesting rôle of imitating ancient Sparta. If the reports of the new law regulating marriage in that State are correct, Minnesota is approaching perilously near Sparta. We are much impressed with the futility, not to say folly, of the proposed law, and wish to chronicle a prophecy that it will fail, as it deserves to do.

This new and preposterous law would make it illegal to marry without a physician's certificate as to the mental soundness of the contracting parties as well as of the families of both of them. It is difficult to know where to begin to criticise such a law. The crusade against cigarettes is as the wisdom of Solon compared with it. We do not stop for a moment to condemn it on ethical and humane grounds; it condemns itself there. To say that any person who had had a parent, a grandparent, or a brother or sister, the victim at some time of an attack of insanity, or epilepsy, should be debarred from marriage by the certificate of a physician, is too wantonly barbarous and too crudely unscientific to need to be criticised at all. We simply point to the utter impracticability of such a law on the ground that the proof of insanity in a family is the hardest to establish and the easiest to conceal of any kinds of proof. All psychiatrists know this from almost

daily experience. Such a law apparently places the happiness of two individuals for life on the scientific acumen and psychiatric skill of the average practitioner of medicine in Minnesota, or leaves the law itself to die a natural death from the inability or unwillingness of a doctor to step in and forbid the banns in the case of some young man or young woman whose mother may have had puerperal insanity, or whose grandfather may have had senile dementia, or whose wayward brother may have just recently died of general paresis. The general sense of mankind will condemn such laws as it has condemned them since the time of the Spartans.

The Bacterial Treatment of Sewage.—The disposal of the sewage of large towns and cities is a problem that has long engaged the attention of public health officials throughout the world. When a town is situated on the banks of a river the natural outlet for the waste from the dwellings and from the manufacturing establishments of that community is into the river which, provided there is sufficient current, will carry the effete matter away from its origin. If, however, there is a second city situated on the same river below the one seeking to dispose of its sewage, the refuse of the first will flow through the second community, giving rise at least to noxious odors. Again, if the second community seeks to obtain its water-supply from this stream, polluted with the drainage from the first, disease will surely follow, and in numerous authentic instances has resulted. Experiments have been made at Barking and at Crossness, in England, with the treatment of sewage by allowing it to flow by intermittent contact through beds made of coke or of ragstone so as to produce in the fluid drainage a series of changes comparable to those found in nature. The object of inducing these changes is to produce an effluent that shall not do harm to the inhabitants when flowing through a stream that is used for the water-supply of a town. The results of these experiments have been reported by Houston (*Edinburgh Medical Journal*, February, 1901). In nature the following cycle of transformation takes place: Dead organic matter decays as the result of the vital activity of bacteria, and ammonia is liberated. The nitrifying organisms bring about the oxidation of the ammonia, first to nitrous and then to nitric acid. These acids, by reaction upon the bases always present, form nitrites and nitrates, and these nourish the living plant. While the nitrogen is undergoing these changes, the carbon of the organic matter is converted into carbonic acid and the hydrogen mainly into water. To some extent, also, the nitrogen and hydrogen are liberated in the free gaseous state. Now the organic matters found in sewage are partly in suspension and partly in solution, and sewage contains in itself the necessary living germs for the destruction of both these forms of organic matter. The object of the biological treatment of sewage is to render the solid matters soluble, by microbial

agencies, and to split up both the matter thus dissolved and the organic compounds that were originally in solution into their simpler elements by the action of living bacteria. In the final process of purification these substances should undergo oxidation, induced by the life processes of nitrifying organisms, and an effluent should be produced that is free from putrescible matter and that contains only inorganic or mineral substances. As compared with the present process of chemical precipitation and sedimentation, the bacterial process presents the following advantages: (1) It requires no chemicals; (2) it produces no offensive sludge, but only a deposit of sand or vegetable tissue that is free from odor; (3) it removes the whole of the suspended matter, instead of only about 80% thereof; (4) it effects the removal of 51.3% of the dissolved oxidizable and putrescible matter, as compared with the removal of 17% by the present chemical treatment; (5) the resultant liquid is entirely free from objectionable smell, does not become foul when it is kept, and maintains the life of fish. Although the effluents from the bacterial beds contained on an average fewer bacteria, liquefying microorganisms, spores of aerobic bacteria, *B. coli*, and spores of *B. enteritidis sporogenes*, than the raw sewage, the reduction was not well marked, and indeed was immaterial, considering the large number of organisms still remaining. It was discovered that the sewage capacity of the coke beds decreased and, in one case, the decrease was determined to be proceeding at the rapid rate of 1% of the original capacity per week. The coke was found to be coated with a black-colored, slimy deposit, free from objectionable smell. When looked at under a low power of the microscope, it was seen to be composed largely of minute particles of sand and coke, together with apparently imperfectly disintegrated animal and vegetable matter. In crude sewage, in bacterial coke beds, and in the effluent from bacterial beds, there are certain bacteria, which, after being stained with hot carbol-fuchsin, resist decolorization with 33% nitric acid. Some of these acid-fast bacteria cannot with certainty be morphologically distinguished from the tubercle-bacillus. In one instance, a guineapig, inoculated with the deposit accumulating on the coke of a bacterial bed, died and presented, on examination, the appearance of death from tuberculous infection. Furthermore, sections of the organs of this animal, when appropriately stained, showed the presence of numerous tubercle-bacilli. In one experiment the cholera bacillus seemed to have lost its vitality in less than a fortnight; in another experiment it remained alive for nearly 4 weeks. Up to the twenty-fourth day after the original inoculation, the presence of *Staphylococcus pyogenes aureus* was readily demonstrated. After experiments with other microorganisms Houston concludes that however satisfactory the process may be from the chemical and practical point of view, the effluents from the

bacterial beds cannot reasonably be assumed to be more safe in their possible relation to disease than raw sewage.

The Therapeutic Monthly.—We called attention in our last number to the fact that a new Journal, devoted exclusively to Therapeutics, would be issued in May under the editorial care of Dr. James Tyson, with whom are associated Dr. Thomas L. Coley and Dr. T. Mellor Tyson. The prospects for the new Journal are most favorable, and we predict success for it.

A Metastatic Tumor Composed of Healthy Tissue of the Thyroid Gland.—Oderfeld and Steingaus (*Medycyna*, January 6, 1901), report the interesting case of a woman, 58 years old, who presented a tumor on the left side of forehead the size of a hen's egg. An incision disclosed a firm mass very rich in bloodvessels, connected with the dura and passing out through the skull. The growth was removed and a microscopic examination showed it to consist of glandular tissue identical with that found in the thyroid gland. No tumor of the thyroid was found. The woman made a good recovery, and no return of the growth was noticed half a year later. The supposition is made that this tumor was the result of metastasis of a piece of healthy thyroid which was carried by the blood to the skull and there developed. [A. R.]

Treatment of Pneumonia by Antidiphtheritic Serum.—Ch. Talamon (*Gaz. Heb. de Méd. et de Chirur.*, February 28, 1901, 48me Année, No. 17) at a meeting of the Société Médicale des Hôpitaux, held January 2, 1901, reported the results of the treatment of 50 cases of pneumonia by the injection of antidiphtheritic serum. Out of these 50 cases, 7, or 14%, died. Formerly in the Hospital Bichet the mortality was at least 24%, and in 1899 it was 37%. The author then gives statistics concerning the ages of the patients and the number in which a history of alcoholism could be obtained. Out of the cases treated before the sixth day, the mean duration of the disease has been 6 days. Twenty-five patients were not treated until after the sixth day of the disease. Six of these patients died. Out of the number who recovered, in 14, a single injection sufficed to produce desferescence. The mean duration of the disease in 18 patients who recovered when treatment was not established until after the sixth day of the disease, was 20 days. The author has injected enormous doses of antidiphtheritic serum, even as much as 200 ccm. or 260 ccm. during several days, and he has never noticed any deleterious results other than erythematous eruption and articular pains and these sequelae were noted only 5 times in the 50 cases. Renal lesions, cardiac lesions and arteriosclerosis are organic defects that demand great reserve in serumtherapy. In this series of cases, however, almost all the patients above 40 years of age suffered from arteriosclerosis, and the author has never observed the least cardiac trouble that could be imputed to the serum; there was no sign of cardiac failure, even in patients between 60 and 75 years of age. The author has never seen an increase of albuminuria after the injections, nor has he observed cases in which that symptom was more persistent than usual; it disappeared, as a rule, as soon as the fever fell. Two or three injections of 20 ccm. each should be given. Ordinarily each injection is followed by a lowering of the morning temperature. If the temperature is high again in the evening a second injection should be made. In cases of adynamic pneumonia with a typhoid aspect, 2 injections ought to be given in the same day, and repeated the next day if the temperature is not modified. In any case the double injection ought to be used if the patient is not seen before the third day of the disease. The author considers that, by following these rules, it is possible to shorten the duration of pneumonia, to suppress or at least to reduce the chances of complications, and to lower the mortality of that disease to about 10%. [J. M.S.]

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA.

Dead in His Chair.—Dr. Jacob E. Hoffer, of Columbia, Pa., died sitting in his chair in the laboratory, death having resulted from heart disease. Deceased was 75 years old.

Farnhurst State Hospital for the Insane.—The Trustees of the State Hospital for the Insane at Farnhurst elected Dr. Florence H. Watson, formerly of the hospital at Norristown, Pa., to be Assistant Superintendent, to succeed Dr. John H. Hammond, resigned.

Duhring Dermatological Society.—The Duhring Dermatological Society has recently been formed with the following membership: Drs. L. A. Duhring, Arthur Van Harlingen, H. W. Stelwagon, J. V. Shoemaker, M. B. Hartzell, J. F. Schamberg, E. S. Gans, C. N. Davis, E. W. Stout, I. M. Koch and J. F. Wallis. Meetings are held on the third Tuesday of each month at the various centrally located hospitals. No papers are read, but cases of rare interest are exhibited and discussed. Dr. H. W. Stelwagon is chairman of the Society, and Dr. J. F. Schamberg, secretary.

Vital Statistics of Philadelphia for the week ended March 30, 1901:

Total mortality	532
	CASES. DEATHS.
Inflammation of appendix 3, bladder 3, brain 15, bronchi 17, kidneys 22, heart 3, liver 1, lungs 78, pericardium 1, peritoneum 7, pleura 1, stomach and bowels 21	172
Inanition 17, marasmus 7, debility 5	29
Tuberculosis of lungs	74
Apoplexy 19, paralysis 9	28
Heart—disease of 42, fatty degeneration of 4, neuralgia of 2	46
Uremia 11, diabetes 2, Bright's disease 10	23
Carcinoma of breast 3, liver 1, rectum 2, stomach 6, uterus 1, face 1	13
Convulsions 15, convulsions, puerperal 1	12
Diphtheria	72
Brain—disease of 2, abscess of 1, dropsy of 1, softening of 3, tumor of 1	8
Typhoid fever	47
Old age	4
Cyanosis	7
Scarlet fever	3
Influenza 9, alcoholism 1, asthma 4, anemia 1, aneurysm of aorta 1, burns and scalds 2, casualties 9, congestion of brain 4, congestion of lungs 5, childbirth 1, cirrhosis of liver 2, cellulitis of leg 1, membranous croup 2, diarrhea 1, dropsy 3, erysipelas 1, extrauterine pregnancy 1, puerperal fever 1, fracture of femur 1, gallstones 1, gangrene, leg 1, hemorrhage, uterus 1, jaundice 3, obstruction of bowels 1, edema of lungs 3, poisoning 1, rheumatism 1, retention of urine 1, arteriosclerosis 1, surgical shock 2, septicemia 6, sarcoma of larynx 1, suffocation 2, teething 4, ulceration of stomach 1, unknown coroner case 1, whooping-cough 3	97
	86

Pathological Society.—The first paper read at the meeting of March 28 was by DR. WILLIAM G. SPILLER on **Cerebellar lesions without cerebellar symptoms.** Several cases were cited as instances of the condition mentioned. Among them were cases of sclerosis of one cerebellar hemisphere, a glioma filling the fourth ventricle with a cyst situated above the tumor, a fibroma above the corpora quadrigemina, sclerosis of nearly the entire cerebellum, etc. None of them produced symptoms that were referable to the cerebellum. The point was made that tumors and abscesses in connection with the cerebellum by pressure on other parts cause symptoms which are not due to the cerebellar lesion. For this reason they are not good cases from which to determine the function of the cerebellum. DR. D. J. MCCARTHY mentioned a case in which practically all the cerebellum was diseased, but no symptoms developed.

DR. D. L. EDSALL reported **A case of malignant endocarditis.** The patient was a girl of 18 who came to the hospital with symptoms of thyroid intoxication. Afterward symptoms developed which pointed to malignant endocarditis or a collection of pus in the region of the kidney. A

definite diagnosis of malignant endocarditis was not made until 5 or 6 days before death when cutaneous and visceral embolism occurred. Streptococci had been found in the blood. Attention was called to the fact that a large quantity of blood should be used when making inoculations. A few drops in agar gave no growth in the above case, but 3 cc. in bouillon gave a culture of streptococci. DR. ROBERTSON spoke of a case of malignant endocarditis in which the only lesion was on the pulmonary valve.

DR. MILTON B. HARTZELL exhibited: 1. **A pigmented epithelioma or alveolar melanotic sarcoma.** 2. **A chronic ulcer showing marked degeneration of epithelium.**

DR. W. B. EATON read a preliminary note on **the histogenesis of myomata.** The various theories of origin were briefly considered. The inclusion theory answers in but few cases, as inclusion is the origin in only about $\frac{1}{10}$ of adenomyomata and that variety is only a small proportion of the whole number of myomata. A study of a number of tumors has been made by Dr. Eaton and in at least 3 of them there was found a genetic relation between the walls of arteries and the tumor. The conclusion reached from the studies thus far made is that many myomata have their origin in the musculature of vessels.

Academy of Surgery.—The meeting of April 1 was addressed by DR. JOHN A. WYETH, of New York, his subject being **amputation at the hip-joint for sarcoma; the tendency to recurrence.** Dr. Wyeth spoke of the extremely malignant character of sarcoma and its liability to recurrence, this being true whether it be the round, spindle, or giant-cell variety. The address dealt largely with statistics of cases of amputation, the percentages of recurrence, the seat of recurrence, etc. Of 131 collected cases of amputation at the hip-joint for sarcoma, 14 resulted in death following operation. Some of these were complicated, however. Leaving out complications the immediate mortality was 6%. Histories of 83 survivors were obtained and in these there were 51 recurrences. Whether the tumor involves the soft parts or the bone has little to do with the safety of the patient. A table giving the length of time after operation of the recurrence was read. The time varied from a few months to 9 years. The study of a case in which Fowler's solution was injected led to the belief that streptococcal infection would cure cases. One exceedingly large recurrence was cured by an attack of erysipelas, the patient now being in health after a lapse of 16 years. Cases of infection were then caused by packing the wound with nonsterile gauze and by inoculating with virulent cultures of streptococci. Cases of sarcoma in the abdomen, at the hip and shoulder were thus treated and some of them are well after the lapse of 8 years. It is difficult to infect these cases even with the streptococcus of Fehleisen. The use of this method is believed to inhibit the growth of some cases of sarcoma, and Dr. Wyeth recommends it in every case. For at least 6 years after operation infection should be induced at intervals not exceeding 6 months. DR. W. W. KEEN spoke of the great mortality of sarcomata and reported 6 cases of amputation, 4 of the upper and 2 of the lower extremity. All died sooner or later. One case, a woman in the fifth month of pregnancy, survived 3½ years. Dr. Keen believes operation should be done in every case. Recurrences are often internal, and are less annoying and painful than the original growth. No operation in continuity should be done. If the tumor be at the lower end of the femur, amputate at the hip-joint. No operation should be done, however, if the hemoglobin be lower than 50%. DR. W. B. COLBY, of New York, reported 6 cases of amputation at the hip-joint. One operated upon in August, 1900, has no recurrence as yet; one could not be traced, and 4 died of recurrence. Operation is advised in all cases, and the toxin treatment by induced infection should be instituted in every case. It is as well to get the patient over the effects of the operation and then give systematic treatment for from 1 to 2 years. Cases were cited in which the patients are well 8 years or less after this treatment. Four cases of round-cell sarcoma have been cured by this method. DR. JOHN B. DEEVER favors treating these cases as open wounds and allowing infection from the start. Of 2 hip joint and 2 shoulder amputations, all died. Of the osteosarcomata, those of the jaw are most favorable. DR. BLOODGOOD, of Baltimore, thinks there may be a difference in malignancy of the various

varieties, the giant cell form being the least likely to give metastasis. DR. YOUNG, of Baltimore, cited a case of sarcoma of the inguinal region and omentum, in which there were recurrent nodules in the chest and other parts of the body. After a time the nodules disappeared, and the patient was found to have pernicious anemia. DR. RODMAN has seen only one case successful—the extirpation of the lower jaw. Toxins should be used in all cases, at once, and not wait for a recurrence. DR. WYETH said that in anemic and run-down cases he would not care to use primary infection by streptococci, but that in robust people he would insist on immediate infection.

Philadelphia County Medical Society.—At the stated meeting, held March 27, DR. C. A. E. CODMAN read a paper on **The acquired form of funnel chest**. Occupation is not considered to be an important factor in the production of this deformity. Some underlying constitutional condition probably aids in cases ascribed to the above cause. Diseases of the respiratory organs, especially obstructive ones, causing pronounced respiratory efforts, have not been given the prominence they deserve as causative factors. Of the 8 cases reported, only one could be ascribed to occupation.

DR. M. G. TULL reported a case of **Arthritis deformans successfully treated by application of ice to the spinal column**. The patient was a female, 21 years of age, who had for months been skilfully treated by other physicians, but with no results. Long ice caps were applied to the spine 2 hours during morning and afternoon at first, afterward 1 hour each time. Guaiacol carbonate was given, and later the iodides. The result was great improvement. The wrist deformities disappeared and the patient can now walk 2 miles. This treatment was also tried in one case of ordinary inflammatory rheumatism with marked improvement in the patient. A notable point was the production of somnolence, insomnia having previously existed. DR. RUGH spoke of the use of hot air in cases of arthritis deformans. He has used it in several cases, some of them for more than a year, with not the slightest beneficial effect.

DR. W. C. HOLLOPETER read a paper on **Fango therapy**. Fango is a grayish-brown slime or mud obtained from certain Italian lakes. It contains iron, sulphur, magnesium, lime, etc., and its properties are not lost by transportation. Its use is indicated in diseases of the muscles, rheumatism, gout, neuralgias, paralysis, etc. Local application to the part affected is made, a layer 3 cm. thick, at a temperature of 98° to 120° being used, the patient being placed between blankets to maintain the heat. After one-half to one hour the fango is easily removed by a tepid bath. Several cases in which this treatment gave good results were reported. Among them were cases of rheumatism, synovial swelling of the knee, gastric disturbance, etc. DR. C. W. BURE said that the indications for the employment of this material were the same as those for a hot poultice. He considers it of no value in diphtheritic or spinal-cord palsies. The chemical composition of the mud probably plays but little part in the effect produced.

DR. I. NEWTON SNIVELY read a paper on the **treatment of croupous pneumonia by antipneumococcic serum**. Several cases were detailed to show the favorable results of this treatment. The serum was given in doses of 20 c.c. every 3 hours in some cases until the temperature was under control. The temperature usually fell by rapid lysis as early as the fifth day in some instances, and was under control even earlier. The use of serum is believed to be of the greatest value in private practice where the cases are seen earlier than in hospitals. Statistics of 106 cases with 13 deaths have been collected. The conclusions reached are that the serum is harmless, and that it gives favorable results, especially in early cases and in those of single infection. Freshly drawn serum should be used if possible. Its use is believed to hasten the crisis. DR. SNIVELY urges all physicians to report their results. DR. J. M. FISHER reported two cases. Two injections of the serum were given daily. One patient, an alcoholic, died the seventh day. The other, a woman, who had croupous pneumonia of one side and some catarrhal involvement of the other is now convalescent. An interesting point in the latter case was the appearance of a rash, a rise of temperature, swelling of some of the joints, etc., after the temperature had been normal,

this undoubtedly being caused by the serum. DR. EDWIN ROSENTHAL uses the serum in large doses even in infants. The symptoms mentioned by Dr. Fisher are often met with. In mixed infections the serum is alternated with antistreptococcic serum. It shortens the attack of pneumonia only in cases that are seen early.

DELAWARE.

Delaware Hospital.—The Delaware Hospital, at Wilmington, has received \$5,000 by the will of Mrs. Sarah Cummins, of Smyrna.

Vigorous Opposition Against the Abbot Bill.—The Abbot bill, which permits physicians who have practised for 10 years in another State, and have resided one year in Delaware, to practise in Delaware without undergoing an examination, is being vigorously opposed by the reputable physicians of that State.

Smallpox.—There are a number of new cases of smallpox reported from the lower part of the State. In Bethel one colored woman died and another (white) dying. There are two new cases at Seaford and one at Concord. In Laurel pickets are patrolling all the town entrances and no one from the stricken towns is permitted to enter. It is believed, however, that the epidemic is abating.

NEW YORK.

Acquitted.—The nurse in Bellevue Hospital who was charged with being responsible for the death of one of the insane inmates, has been acquitted.

Smallpox on an Ocean Steamer.—The Anchor Line steamer *Bantana*, which arrived on March 26 from Marseilles and other Italian ports, was quarantined on account of a case of smallpox which existed among the passengers, the patient is convalescent and has been removed to North Brother Island. The New York authorities are to be commended for their promptness in discovering the disease.

Loomis Sanitarium.—The Charitable Annex in connection with the Loomis Sanitarium, at Liberty Heights, Liberty, Sullivan county, New York, was opened on Friday, March 22, 1901, with 12 patients. The present capacity of this annex is 24 patients. The patients are charged \$5 a week, for which they receive their board, lodging, medical attendance, medicines, and laundry; they also derive all the benefits of the main sanitarium in the way of scientific care and oversight. The deficit between the \$5 a week charged to patients, and the actual cost of maintenance, is made up by a maintenance fund raised annually by subscription. While the financial affairs of the annex are administered from the main sanitarium, there is a superintendent in charge there. Dr. J. Edward Stubbett, physician in charge at the main sanitarium, visits the annex once a week as consulting physician, while Dr. Stephen W. Wells, resident house physician, and Dr. Thomas I. Shannon, resident assistant house physician at the main sanitarium, constitute the regular visiting staff of the annex, visiting it daily and keeping daily office hours. The nurses are furnished from the training school of the main sanitarium. This annex has a thoroughly equipped treatment room, and the patients receive practically the same treatment that is given at the main sanitarium. At present there is one large 3 story building, and it is the hope of the management to be able to raise sufficient funds in a short time to enlarge the institution, so that many more patients may be cared for. The various medical examiners for the main sanitarium will also examine applicants for admission to the annex, but the rules for receiving only incipient cases are even more rigidly enforced here than at the main institution.

NEW ENGLAND.

Donation to Yale Medical College.—\$100,000 was recently given to Yale University for the purpose of constructing a building for the medical school. The name of the donor has not been made public.

WESTERN STATES.

Unique Bill.—A bill was recently introduced in the legislature of Arkansas preventing physicians from practising if they use intoxicating liquors in beverages.

Senator Chilton's Bill Passed.—By the passage of this bill the State of Minnesota prohibits the marriage of the insane, the epileptic, and the idiotic, and requires a medical certificate from all applicants for marriage licenses. Amendments were adopted permitting the marriage of all feeble-minded persons over 45, the bill originally reading that this permission was only to be extended to women.

Bubonic Plague in San Francisco.—Not long ago a Government commission, consisting of Professor Flexner, of the University of Pennsylvania, Professor Barker, of the Chicago University, and Professor Novy, of Ann Arbor University, was sent to San Francisco by the Government to investigate the reports of bubonic plague. Six fatal cases were reported between February 5 and 12 by this special commission. The report of the commission confirms the presence of the plague which occurred among Chinamen in San Francisco. In the report, under the heading of remarks it is stated: "Plague has been reported in San Francisco officially in the Public Health Reports since March 6, 1900, 32 cases (all fatal) having been reported and published in previous numbers of the Public Health Reports, and the facts were reported in the annual report to Congress of the Secretary of the Treasury, dated December 4, 1900."

The San Francisco Medico-Chirurgical Society.—Regular meeting February 4, 1901, Dr. Jos. O. Hirschfelder in the chair.

Leprosy—Mixed Variety.—DR. C. F. GRIFFIN presented a young patient and gave the following history of the case: Boy, 13 years old, French parentage; native of Papeete, Tahiti. Was brought from the islands 5 months ago for treatment for "general weakness." Patient perfectly well until two years ago, when he stepped upon a dirty white coral with the left foot, making a cut through the skin about an inch long. The wound bled freely; patient applied a native plaster dressing of herbs, for about 6 months. The foot swelled, requiring constant dressing of cloths around it. He walked for about 6 months; then saw a European doctor, from a French war ship, who cut the wound, and sponged out one-half teaspoonful of some black material, leaving a hole about the size of a 10-cent piece, running down to the bone of the end of the second toe.

During this time the spots now present on the extremities and the face began to appear; first behind the ears, and the ears began to grow larger. The sequence of these events is unknown. No spots appeared upon the chest, back nor abdomen. The toes and foot swelled, but the legs and thighs did not swell. Cough, and loss of weight, and night sweats began two years ago, at which time, also, the nose began to be sore and somewhat swollen. Has had at irregular times since, bloody nasal discharges. No other illness in family. The maternal grandmother died at the age of 58, after having some operation upon the nose.

Physical Examination.—Boy about medium size, and development to be expected at his age. Face presents nothing of note except a purplish discoloration over the left malar eminence. The skin over and around the spot feels smooth, indurated, much as would be felt in a malignant tumor involving the skin previous to ulceration. The ears are unusually large, stand out from the head, having about them the suggestion of akromegaly. Upon the ears and about the forearms are a few spots resembling psoriasis. Impaired resonance and bronchial breathing of both apices. Weight absolute, 61½ pounds. Diagnosis: Tuberculosis pulmonalis and psoriasis. Tonic and supportive treatment resulted in increase of weight, subsidence of cough, and discontinuance of night sweats. Local treatment for the spots, chrysophanic acid in ointment.

From time to time the case was seen. The spots becoming not smaller, but increasing in number, called special attention to them, when wide areas of analgesia and anesthesia were found over the arms, parts of the face and lower extremities. Coverslip smear preparations were then made and stained, establishing a diagnosis of tubercular leprosy, which diagnosis was confirmed by sections cut from a papule on the forearm.

This case is brought before you for three reasons: First, to show what, here in San Francisco, is a somewhat infrequently seen disease—leprosy; second, to call attention to the ease with which the disease may be unthinkingly or carelessly diagnosed as psoriasis; third, the ease with which, when once attention is drawn in that direction, the diagnosis may be made by the aid of the microscope.

The following is the simple technic followed, and is usually successful because the bacillus of leprosy is found in the ulcerating skin lesions, in the discharge from them, and in the bloody serum from them, and not in the general bloodstream of the patient. The crust or superficial layers of skin over a papule, being gently removed, a clean cover-slip is touched lightly to the oozing surface, it is then dried and stained with carbolfuchsin, in the same manner as for tubercle bacilli. The lepra bacilli, are easily decolorized by subsequent washing in alcohol, or in weak solutions of mineral acids. This characteristic distinguishes them from tubercle bacilli. Essentially the same technic may be applied to discharges from the nose.

SOUTHERN STATES.

Pasteur Department of the Baltimore City Hospital.—A report from the Pasteur Department of the Baltimore City Hospital states that up to date 200 cases have been treated, in 120 of which the animal had been demonstrated rabid by subdural inoculations of rabies. There has been but one death from any cause; that was rabies. The Pasteur Department of the City Hospital was founded by the College of Physicians and Surgeons for the preventive treatment of hydrophobia according to the Pasteur method. It is modeled after the "Institut Pasteur," of Paris. The method is the result of personal investigation at that institute and is identical with that used in Paris. Without the Pasteur preventive treatment the mortality from bites of rabid animals is 16 to 25%. Of those treated by the Pasteur method, the mortality is about $\frac{1}{15}$ of 1%.

Program of American Gastroenterological Society.—The fourth annual meeting of the American Gastroenterological Association will be held in the banquet hall of the "Shoreham," Washington, D. C., Wednesday, May 1, 1901. Council meets at 9 A.M. Morning session at 10 A.M.

1. Address by the president, Dr. Max Einhorn.
2. "The German Clinics of Today," Dr. J. C. Hemmeter.
3. "The Etiology of Hepatic Sclerosis," Dr. A. L. Benedict.
4. "Treatment of Gastric Ulcer," Dr. D. D. Stewart.
5. "The State of the Gastric Secretions in Chronic Rheumatism and Rheumatoid Arthritis," Dr. Frank H. Murdoch.
6. "Some Cases of Tetany," Dr. William Geary Morgan.
7. "The Report of Two Cases of Acute Dilatation of the Stomach," Dr. Julius Friedenwald.
- 1 P. M. Luncheon. 2:30 P. M. Afternoon Session.
8. "Experiments in Peristalsis," Dr. Fenton B. Turck.
9. "Some Clinical Studies in Gastric Secretion," Dr. G. W. McCaskey.
10. "Treatment of Antonia Gastrica Splanchnoptosis by Means of Abdominal Strapping," Dr. A. Rose.
11. "Hyperchlorhydria," Dr. John A. Lichty.
12. "Report of a Case of Cancer of the Cardiac End of the Esophagus at a Distance of Twenty Inches from the Incisor Teeth in a Man Five Feet and Three Inches Tall," Dr. C. D. Spivak.
13. "Digestive Disturbances in Formes Foustes," Dr. John P. Sawyer.

Vital Statistics of Havana.—In his report of the vital statistics of Havana for the month of February, Major W. C. Gorgas, Chief Sanitary Officer of the Department of Cuba, states that the mortality in Havana for that month is less than it has been for any February of which any reliable record is at hand. The minimum was in 1893, when there were 446 deaths, and the maximum in 1898, when there were 1,602 deaths. The rate per thousand—19.32—makes even a better showing. The last February of the Spanish rule, 1898, gave us a death-rate of 82.32 per thousand. February of 1901—the third February under American rule—gives us a death-rate of 19.32. This is a very creditable death-rate, and

places Havana in the class of healthy cities of the world. Many of the cities of the United States and Europe have a higher mortality than this. According to the latest figures of Marine-Hospital reports Baltimore, with a population of 334,489, for the week ending January 26, had 225 deaths—a death-rate of 26.93; Cincinnati, population 326,000, for the week ending January 25, had 142 deaths—death-rate 22.65; Boston, population 560,892, for the week ending January 26, had 260 deaths—death-rate 24.10; Jacksonville, population 17,201, for the week ending January 19, had 16 deaths—death-rate 48.37; Newark, N. J., population 246,070, for the week ending January 19 had 107 deaths—death-rate 22.61; New Orleans, population 287,000, for the week ending January 19, had 156 deaths—death-rate 28.26; New York, population 3,437,202, for the week ending January 26, had 1,432 deaths—death-rate 22.42; Washington, population 278,719, for the week ending January 19, had 141 deaths—death-rate, 26.60; Belfast, Ireland, for the week ending January 5, had 165 deaths, with a death-rate of 23.90; and Mobile, population 38,469, for the week ending January 16, had 22 deaths—death-rate 29.78. It will be seen that most of the cities have a much higher death-rate than Havana. Major Gorgas states: "Jacksonville, Mobile, and New Orleans, all have a higher death-rate than Havana, and I have no doubt that we would find such to be the case with other Gulf cities if we could get statistics on the subject. At present they look upon Havana with suspicion, but I think that in the near future, Havana will have to guard against them. Taking cities in the yellow-fever area, such as New Orleans, Mobile, Pensacola, Tampa, Key West and Havana; those in bad sanitary condition, as shown by their high death-rate, would be more likely to become infected than a city such as Havana, which is in first-class condition as shown by its low death-rate. I think it probable that within a year or two, Havana will have to take steps to protect itself from the above mentioned cities. During February of 1900, we had 17 new cases of yellow fever; in February of 1901, we had 8 new cases. As the number of nonimmunes was very much larger in February of this than in that of last year, I think the showing is very encouraging. Besides disinfecting the houses with formalin and other disinfectants, we now screen the rooms occupied by a yellow-fever patient as soon as his case is reported, and kill all the mosquitoes in the building with the fumes of pyrethrum powder, at the same time covering with kerosene oil all places where mosquitoes can breed about the building. We also kill the mosquitoes in all the adjoining buildings in the same way. With these measures and the steps we are taking to kill the mosquitoes in the suburbs, I hope to markedly decrease the yellow fever during the coming summer."

MISCELLANY.

Correction.—In the abstract in the article of Drs. Ravenel and Gilliland (*University Medical Magazine*, February, 1901), which appeared on page 607 of our last issue, the statement was made, concerning the disinfectant and deodorant action of ammonium persulphate, that it has little, if any value as either. This conclusion applied to **potassium persulphate**. The studies of the investigators have demonstrated that **ammonium persulphate** possesses most decided germicidal properties, and is a most excellent deodorizer. In some ways it is superior to carbolic acid as a germicide.

Obituary.—DR. EDWIN C. BALEWIN, at Dover, N. J., on March 25.—DR. P. H. COOK, at Vicksburg, Miss., on March 26, aged 87 years.—DR. S. EDGAR MORTIMORE, at Jacksonville, Fla., on March 21, aged 56 years.—DR. MONTGOMERY LAWRENCE, at Baltimore, Md., on March 26, aged 70 years.—DR. Changes in the Medical Corps of the U. S. Navy, for the week ended March 30, 1901:

LEDBETTER, R. F., assistant surgeon, detached from the "Constellation," April 1, and ordered to the "Chicago," via the "Dixie," April 3, as relief of Assistant Surgeon J. R. Whiting.
CRAWFORD, C. A., assistant surgeon, detached from the "Dixie," March 28, and ordered to the "Constellation," April 1, as relief of Assistant Surgeon R. E. Ledbetter.
WHITING, J. R., assistant surgeon, detached from the "Chicago," upon reporting of relief, and ordered to the "Dixie."
PICKRELL, G., surgeon, detached from the Naval Hospital, Mare Island, Cal., and ordered home.
EVANS, E., assistant surgeon, detached from the Naval Hospital, Mare Island, Cal., with permission to delay en route home.
McCLANAHAN, R. K., assistant surgeon, ordered to the Asiatic Station, via the "Solace," April 12.
DECKER, C. J., surgeon order detaching from the "Monocacy" and ordering to the "Oregon" revoked; ordered to the "Newark."
LEACH, P., surgeon, order detaching from the "Oregon" and to the "Monocacy" revoked.
HIBBETT, C. T., surgeon, detached from the "Newark" and ordered to the Naval Hospital, Cavite, P. I.
SPEAR, R., passed assistant surgeon, detached from the "Isla de Luzon" and ordered to the "Concord."
EVANS, S. G., passed assistant surgeon, detached from the "Concord," and ordered to the "Monocacy."
GROW, E. J., assistant surgeon, detached from the "Glacier," and ordered to the "Isla de Luzon."

Changes in the U. S. Marine-Hospital Service, for the week ended March 28, 1901:

MURRAY, R. D., surgeon, granted leave of absence for 5 days from April 9, 1901. March 23.
AUSTIN, H. W., surgeon, detailed chairman of a board, to be convened from time to time as necessary, for the purpose of reexamining rejected immigrants. March 28.
EAGER, J. M., passed assistant surgeon, upon expiration of leave of absence to proceed to Naples, Italy, for duty, relieving Assistant Surgeon V. G. Heiser. March 25.
MATHEWSON, H. S., assistant surgeon, granted leave of absence for 3 days from March 29. March 26.
CLARK, TALIAFERRO, assistant surgeon, granted leave of absence for 30 days, on account of sickness. March 22.
LAVINDER, C. H., assistant surgeon, granted leave of absence for 10 days from March 28. March 27.
McMULLEN, JOHN, assistant surgeon, upon being relieved from duty at Wilmington, N. C., to proceed to the Mullet Key Detention Camp, Florida, and assume command, reporting, en route, at Washington, D. C. March 28.
RUSSELL, H. C., assistant surgeon, granted leave of absence for 28 days from February 21, on account of sickness. March 22.
HEISER, V. G., assistant surgeon, upon being relieved from duty at Naples, Italy, to proceed to Washington, D. C., and report in person for duty. March 25.
GOODMAN, F. S., hospital steward, to report to the Director of the Hygienic Laboratory, Washington, D. C., for duty. March 20.

The Use of Tiokol in Tuberculosis.—Achswlediani (*Woenno Medicinski Journal*, December, 1900) determined to try this new remedy so extravagantly lauded by Shwartz, de Renzi, Maramoldi and others. He made careful observations in eight cases in which incipient tuberculosis was present. The following results were obtained: (1) The temperature, pulse, respiration and urine were in no way modified by the drug; (2) the amount of expectoration did not diminish; (3) the weight was reduced; (4) no changes in percussion or auscultation were observed; (5) the number of tubercle bacilli increased; (6) the night-sweats remained the same; (7) the debility and cough remained in statu quo. [A. R.]

Two Cases in which Dead Fetuses Remained in the Uterus for a Considerable Time.—A. P. Petrow (*Russki Medicinski Vestnik*, February, 1901) reports the following interesting cases: In one the woman, 34 years old, had a number of miscarriages as a result of syphilis contracted from her husband. Her last pregnancy led to a division of opinion among the physicians, some claiming that she was pregnant while others diagnosed a fibroid. On the seventh month, after a considerable period of exhaustion accompanied by other alarming symptoms, the woman was delivered of a male fetus partially mummified, presenting the developments of 3½ months. In the second case a macerated fetus of 5 months was delivered 2½ months after it died. This woman was also syphilitic. In both cases the mothers recovered. [A. R.]

foreign News and Notes.

GREAT BRITAIN.

Royal College of Surgeons.—At a meeting of the Fellows of the Royal College of Surgeons in Ireland, held on Tuesday, March 19th, Sir William Thomson and Mr. Robert H. Woods were elected members of the Council.

World's Tuberculosis Congress.—American medical scientists will be both numerous and prominent at the World's Tuberculosis Congress, to be held in London during the last week in July. Professor William Osler, of Johns Hopkins University, has been invited by the management of the congress to organize the American contingent. Among those who have already signified their intention of coming are Professor Trudeau of Massachusetts, Professor Solly of Colorado, Dr. Herman Biggs of New York, Dr. J. G. Adami of Ontario, and Professor McEachran of Quebec. Professor Koch of Berlin and Dr. Brouardel of Paris, Europe's great bacilli authorities, have announced their intention of actively participating. Dr. Malcolm Morris, of London, the originator and secretary general of the congress, said recently: "Certainly tuberculosis never called together so distinguished a body of international experts. Delegates will attend from probably every civilized country of the world."

Plague.—The *British Medical Journal* says plague seems to be obtaining a serious hold upon Capetown. Fresh cases, varying in number from 2 to 17, have occurred daily during the last fortnight. The information is incomplete, and a compilation from telegrams gives the number of fresh cases on March 7, 9, 10, 12, 15, and 18 as 8, 6, 10, 17, 11, and 5 respectively. The importance of the outbreak of plague at the Cape is surely sufficiently great to make it reasonable to ask the Government for exact information. A telegram, dated March 19, from the Governor of Cape Colony to the Colonial Secretary states that the plague report for the week ending March 16 is as follows: "Cases admitted 81, deaths 29, suspects 17, contacts 402." The report, it would appear, applies to the whole Colony, but contains no information as to where the deaths or cases have occurred, nor as to whether the patients are white, negro, Indian, or Malay. Plague at the Cape has struck the empire in a most vital spot, and any failure to issue adequate official information as to the prevalence of the disease is not consistent with imperial necessity. We would urge the Government to keep nothing back, but to let the people in this country know the exact state of affairs in regard to the plague at the Cape and in South Africa generally. The Malay laborers have been giving trouble, refusing to go to hospital, to live in isolation camps, or to have their houses inspected. As there are several thousand Malay males in the city, their turbulence is calculated to cause trouble and difficulty. The Kaffirs have already been sent to isolation camps, and as the Government has prohibited the meeting of more than 25 persons, the proposed meeting of natives to protest against the plague measures is prevented.

More About Huxley.—The anecdotal side of a great man's biography is, if not the most important, at least the most attractive. Professor John Fiske, in a recent number of the *Atlantic Monthly*, gives some interesting reminiscences of Huxley. The following anecdotes will be appreciated by all medical readers:

A clergyman, who had no knowledge of biology, wrote a foolish attack on the Darwinian theory and was rather piqued that Huxley took no notice of him. He thereupon wrote to the latter calling his attention to the article and asking his advice as to further study of these deep questions, whereupon Huxley answered briefly and to the point, "Take a cockroach and dissect it."

One evening Professor Fiske discussed with Huxley the celebrated murder of Dr. Parkman by Dr. Webster. It will be recalled that Webster murdered Parkman in his lecture room in Harvard Medical College about 1849 and attempted to destroy the remains by chemical reagents. Fiske expressed surprise that Webster, who was an expert chemist, should have been so slow and bungling in getting rid of the

remains; whereupon Huxley said, "Well, there is a good deal of substance in a human body. It is hard to dispose of so much *corpus delicti*. I have often thought this when I felt like killing somebody."

On another occasion he examined a student who insisted on placing the mitral valve in the right side of the heart. Huxley expressed sympathy with him and told him that he had himself always made the same mistake until it occurred to him one time that a bishop was never in the right.

At the close of a lecture he once asked a student if he understood it all. "All, sir," answered the student, "but one part, during which you stood between me and the black-board." "Ah," replied Huxley, "I tried my best to make myself clear, but evidently I did not make myself transparent."

CONTINENTAL EUROPE.

Influenza in Copenhagen.—There were 1700 cases of influenza reported in Copenhagen last week. Several deaths have been reported. In general, however, the effect of the disease is similar to that seen in America, most of the cases being of a rather mild character.

Student Riots in Russia.—On account of the student riots which have lately occurred in Russia, the courses for women medical students have been stopped.

Postmortem Examination of the late Prof. Pettenkofer.—The *British Medical Journal* states that an autopsy performed on the late Prof. von Pettenkofer by Prof. Bollinger showed the presence of chronic inflammation of the dura mater, considerable calcareous deposits in the cerebral arteries, and chronic arthritis deformans; gallstones were found in the gallbladder.

Turpentine Poisoning.—Schulz in studying the toxicological effects of turpentine states that the inhalation of a small amount of turpentine is liable to be poisonous as small quantities are very rapidly absorbed. The poisoning generally affects the central nervous system. The symptoms produced were extreme muscular fatigue, headache, low pulse, digestive disturbances, constipation, and in two cases marked acne.

Cocain Habit.—The cocain habit is becoming quite prevalent in Bengal, and efforts are being made to restrict the sale of the drug, which the Hindus are using as a substitute for opium.

University of Warsaw.—The total number of students in the University of Warsaw in the current semester is 1,169. Of these 367 belong to the Faculty of Medicine.

Italian Medical Congress.—The Italian Congress of Internal Medicine will this year hold its annual meeting at Pisa in the latter half of October.

MISCELLANY.

A Typical Russian Episode.—The *Vratch* quotes from the *Kurier* the following characteristic story: An architect and a physician accused of disturbing the peace and insulting the police appeared before the justice of the peace in Moscow. The circumstances of the case were that a woman was run over by a car which crushed her leg. Two policemen who happened to be present sent for the ambulance. Meanwhile the woman was lying on the track, bleeding profusely. The ambulance was slow in coming. The people who gathered around became indignant at the indifference of the policemen. The prisoners were especially demonstrative and one of them, the physician, took out a handkerchief and tied it around the woman's leg. The ambulance arrived only half an hour later and removed the almost exsanguinated woman to the hospital, while the two gentlemen who were "disturbing the peace" were taken to the police station. They were discharged, however, their excited state of mind being considered as an extenuating circumstance.

Professor W. A. Manasein, the distinguished editor of the *Vratch*, died February 13, from thrombosis of the cerebral bloodvessels, caused by a chronic nephritis. The deceased

had been editor of this excellent Russian weekly for over 21 years. In him the Russian medical profession loses an able teacher, a noble man, an upright and fearless editor, and a leading spirit. Medical journalism, not only in Russia, but all over the civilized world, will surely miss in him one who had succeeded in making his journal the representative organ of universal medicine in general, and Russian in particular. By his will the *Vratch* is to be issued until the end of the year and then discontinued, he having been also the publisher for the past 6 years. Until then Dr. S. Wladislawlew is to be the editor.

The Effects of Canadian Hemp in Heart Disease.

—Golubinin (*Klinicheski Jurnik*, December, 1900; *Vratch*, Vol. xxii, No. 4) found as a result of a number of observations, four of which are described in detail, that a fluid extract of Canadian hemp diminishes the frequency of the pulse-rate in severe cases, while the organism is under its influence, but in milder cardiac affections, even after its use has been discontinued, the blood-pressure is raised, the secretion of urine, in favorable cases, is considerably increased and the albuminuria, in so far as it depends on the blood-pressure, disappears. The number of respirations also diminish in proportion to the improved circulation. The fluid extract should be administered in doses of 5 drops 3 to 4 times daily. No untoward effects take place. The slight irritation of the stomach quickly disappears after the drug has been discontinued for one or two days. To prevent the gastric irritation, an equal amount of an infusion of *cannabis indica* should be administered. The author concludes by stating that in Canadian hemp we have a most valuable remedy which gives relief in many severe cases not benefited by other cardiac remedies. [A.B.]

Tuberculosis of the Submaxillary Gland.—Arcoleo (*Morgagni*, September, 1900) states that tubercles in the submaxillary gland are particularly liable to become fibrous. Whether the bacillus gains ingress by lymph- or blood-channels, there is always a firm encapsulation due to chemotaxis, the leukocytes becoming deposited in the connective tissue stroma of the gland. These leukocytes, as well as the connective tissue cells, subsequently assume the character of epithelial cells. It is difficult to artificially infect the gland with tubercle bacilli by inoculation through the salivary duct. The tuberculous nodes form in the center of the lobule; the sclerotic change begins in the perilobular tissue and extends towards the center. Direct inoculation of tubercle bacilli causes tubercular abscesses and lesions, which quickly result in sclerosis of the gland. [M.R.D.]

On Moore's Ureine and its Physiologic Action.—Kuliabko (*Vratch*, Vol. xxii, No. 4) presented before the Russian Society for the Preservation of Public Health the results of his investigations of ureine, a substance claimed by Dr. Moore to be a newly-discovered important urinary constituent. The author found that this so-called ureine possesses no chemical entity. The method of obtaining it is extremely inaccurate, and there is no assurance of the purity of the substance obtained. "Ureine" contains a great deal of water, urea, and other urinary constituents, representing practically a watery-alcoholic extract of urine. The toxic effects of "ureine" on animals resemble generally the action of urinary extractives. It affects the nervous system and, principally, the respiratory center, the immediate cause of death being due to paralysis of respiration. When injected directly into the blood-current it lowers the blood-pressure, diminishes and finally paralyzes respiration, producing general convulsions. The latter, however, are due to the respiratory difficulty and are not observed when artificial respiration is used. In this case there take place increased secretion of the glands, frequent urination, diminished sensibility, disturbances of respiration and dilatation of the pupil. Owing to the large amount of urea this substance contains, it is extremely irritating to the muscles or nerves when applied locally. Dr. Dzershowski, one of the members of the society, remarked that in his opinion "ureine" does not merit the attention it received. In its preparation Dr. Moore employs oxalic acid, mercury, ammonia, etc. These substances are not removed and the preparation therefore is impure. [A.B.]

The Latest Literature.

British Medical Journal.

March 16, 1901. [No. 2098.]

1. An Address on the Causation of Cancerous and Other New Growths. J. GEORGE ADAMI.
2. On the Occurrence of Pyrexia in Cancer and Other Diseases of the Liver and in Cases of Gallstone. C. O. HAWTHORNE.
3. Digestion Leukocytosis in Cancer of the Stomach. CARSTAIRS DOUGLAS.
4. The Palliative Treatment of Carcinoma Uteri. GERALD R. LEIGHTON.
5. The Application of Romanowsky's Stain in Malaria. MAJOR W. B. LEISHMAN.
6. The Milroy Lectures on the Influence of the Dwelling Upon Health. JOHN F. J. SYKES.

1.—After a consideration of the different theories to account for the causation of cancerous and other new growths, Adami concludes that whatever the origin of a tumor, however it is started, that which makes the tumor is the assumption by the primary cells of that tumor of the habit of growth in place of the habit of work, and according to the extent of this replacement, we get the various grades of tumor formation from the most benign to the most malignant. The katabolic activities of the cell are of two orders: those that determine the relationship of the cell to the exterior, and those that are vegetative and that determine the continued existence and multiplication of the cell. The former activities are excited by stimuli of various orders from without; the latter are only indirectly so excited, but are more directly called into play by conditions obtaining within the cell. The nucleus is the controlling agency in the higher katabolic activities of the cell at least, both functional and vegetative, and nuclear activity is accompanied by breaking down and discharge or by rearrangement of the nuclear molecules. The changes that occur in the nucleus during the active performance of the specific functions of the cell are of a character so different from those observed during the process of cell division that proliferation and active performance of specific function are incompatible to a great degree. It follows, therefore, that active cell division and cell proliferation occur only in conditions in which the cell cannot fully utilize the assimilated material and the energy stored up in the assimilation of that material in the performance of its specific functions. Such conditions are to be met with when the tensions acting on the cell are reduced and certain energies that were formerly necessary to counteract opposing forces are freed and thus become capable of diversion from their purpose, or when stimulation from without results in increased assimilation and storage of nuclear and cell material which from any cause cannot be utilized in the performance of specific function. In either case, the cells will continue to proliferate so long as the primary modification of physical relationships or the primary stimulus continues to act, so long as there is adequate nutriment, and so long as the tensions exerted upon the cells do not become excessive. Provided that these conditions are observed, the greater the amount of cell proliferation, the greater the tendency for certain at least of the newly formed cells to be projected from the relations proper to cells of the tissue giving them origin, and the less will be the opportunity for such cells to carry on their primordial function. The longer the cells are diverted from their proper extrinsic functions to proliferative activity, the greater the momentum acquired by them to continue performing the proliferative act until the functional activities become largely suspended and the habit of growth is set up. When this habit of growth is inaugurated the cells can continue to grow and multiply in the complete absence of those conditions that initiated their proliferation in the first place, and we obtain that purposeless, functionless cell growth characteristic of the true tumor. According to the stage of cell development in which this habit becomes impressed upon the cell, we have the various grades of benign and malignant tumors. According to this theory, microorganisms and their products may be one of the causes originating localized cell prolifera-

tion, provided that they bring about stimulation rather than irritation, or irritation of so mild a type that the cells are stimulated to an increased metabolism which, however, does not go on to exhaustion and excessive breaking down of protoplasm, and provided also, that the microorganisms and their products continue in action for a sufficiently long time to set up the habit of growth. It is quite conceivable that such microorganisms may continue to exist in the tumors they originated, exerting a cumulative effect. The more the cells depart from the type the greater the effect of these microorganisms and their products in producing a tissue of rapidly proliferative and malignant type. This continuance and persistence of microorganismal action, however, must not be regarded as essential. The very fact that after all these years and after the hosts of careful observations, we are still in very grave doubt as to whether any of the bodies seen in tumors are really parasites, the fact that no growth of these bodies have surely been obtained outside the organism and then, upon injection, have induced tumor formation, although by no means proof absolute, may be quoted in favor of the view that if microorganisms originate malignant tumors, they do not continue in them in the living state. It is quite possible, according to this theory, that certain specific forms of microorganismal life originate certain forms of tumor growth and that, like other pathogenic microorganisms, these may show a predilection to attack special tissues under special conditions; and, if it be true that malignant growths are specially common in certain localities, then such microorganismal origin becomes eminently probable. But if this theory be true, it does not follow that, discovering the causative microorganism, we shall be able to arrest the development of carcinoma by antimicrobial or antitoxic means. But above all, the author feels that the greatest benefit to the patient and the greatest triumph and satisfaction to the practitioner will, for some years to come, be the recognition and successful removal of malignant tumors at the earliest possible date, and the removal of benign tumors, in general, before they have taken on possible malignant characters. [J.M.S.]

2.—Hawthorne publishes abstracts of the course of several cases that show that a considerable degree of pyrexia may attend carcinoma of the liver. As a result of these clinical observations it follows that the distinction of carcinoma of the liver from impacted gallstone, abscess, and other hepatic conditions in which febrile disturbances more or less frequently occur, is not facilitated. But the recognition of this clinical truth may at least save the physician from an inclination to place undue stress upon the existence of pyrexia as a reason for excluding carcinoma from the diagnosis. A combination of jaundice, intermittent fever, and hepatic enlargement should demand very careful consideration before the diagnostician decides to cast the verdict for gallstone, on the one hand, or malignant disease on the other. In the various forms of abscess of the liver, rigors and remittent or intermittent fever is to be expected, but this expectation is not always realized. Identical symptoms have followed the bursting of an hydatid cyst with the passage of secondary cysts into the bile-duct. The same association of events has followed the entrance of lumbricoid worms into the biliary passages. Pyrexia occasionally exists as a symptom of hepatic cirrhosis. [J.M.S.]

3.—Douglas reports the result of a study of the blood-formula in 11 cases of malignant disease involving the stomach. It would appear from the results of the investigation that digestion leukocytosis is a broken reed on which to lean in the diagnosis of carcinoma of the stomach, since only a trifle over 54% of the cases give a positive reaction. Out of the 11 cases, digestion leukocytosis was absent in 6, or 54.54%; present in 4, or 36.36%; and inconstant in 1, or 9.10%. [J.M.S.]

4.—Leighton considers the palliative treatment of carcinoma uteri as illustrated by a case which had been under almost daily observation for 2½ years from the first diagnosis of the disease to its fatal termination. His main treatment consisted in the administration of the solution of the hydrochlorate of morphin alternating with chloral hydrate and morphin suppositories. Subsequently the liquor morphiæ was discarded for the tincture which was carried to its limit, and was associated with tincture of belladonna. The suffering of the patient was inconsiderable. [W.A.N.D.]

5.—Leishman describes a modification of Romanowsky's method of staining for the demonstration of the presence of malarial parasites in the blood and, in particular, for the differential diagnosis of the tertian parasite. The chief advantages of the method are: 1. The specific action of the stain upon all red blood-corpuscles infected by the tertian parasite. 2. The greater certainty of the detection of very young intracorporeal forms of all varieties of the malarial parasite. 3. The facility with which the occurrence of a mixed infection may be detected. 4. The ease of application, after a little practice, and the certainty of the results obtained. In the preparation of the blood film care should be taken that the cover-glasses are never subsequently handled except with a pair of forceps, as the slightest trace of moisture from the fingers will endanger the result. A thin even film is necessary and this should be fixed in equal parts of ether and absolute alcohol. The fixed film should be washed well in water and dried in the air before staining. Two stock solutions are prepared; the first is a 1% solution of methylene blue in distilled water which is rendered alkaline by the addition of 0.5% of sodium carbonate. This solution should be heated for some time before use. To prevent the growth of moulds 0.25% of formalin may be added. The second solution is a 1 to 1,000 solution of eosin in distilled water. A portion of each of these solutions is further diluted with 24 parts of distilled water and an equal volume of each diluted solution is poured on to the cover-glass in such a way that they come in contact with the film at the moment of mixing. At the end of half an hour, the film is removed from the stain and examined in water by a $\frac{1}{4}$ or $\frac{1}{8}$ inch objective. If, instead of a deep, red color, the nuclei and blood plates are only purple or deep violet, the staining is insufficient, and the films must be replaced in the solution for a short time. The deep, red color represents a slight degree of over staining and the preparation should be decolorized, after washing in water, by rinsing in absolute alcohol for 2 or 3 seconds, the cover glass should then be immediately transferred to water until all traces of alcohol are removed. Decolorization may be accomplished by holding the film under running water for some time, or by leaving it to soak in water for from $\frac{1}{2}$ hour to an hour. The appearance of the film when it is ready to mount should be as follows: The red cells are transparent and nearly colorless, or, perhaps, slightly green or pink. The polymorphonuclear leukocytes have their nuclei stained ruby red or magenta, the extranuclear portion being colorless or containing a few reddish granules. The nuclei of the mononuclear leukocytes and lymphocytes are of the same color as those of the polymorphonuclears, and their margins are very clearly defined, while the extranuclear portion is stained a beautiful eau-de-nil or pale blue color. The blood plates are ruby red, with definite involuted margins. The films are now dried in the air or by gentle heat and mounted. [J.M.S.]

6.—Will be abstracted when finished.

3. Some Personal Experiences of the Epidemic of Enteric Fever Among the Troops in South Africa, in the Orange River Colony. H. H. TOOTH.
4. The Clinical and Pathological Relations of the Chronic Rheumatic and Rheumatoid Affections to Acute Infective Rheumatism. ARCHIBALD E. GARROD.
5. The Toxicological Detection of Arsenic and the Influence of Selenium on its Tests. WILLIAM HENRY WILCOX.
6. Septic Disease in Graduated Attacks in the Same Patient. J. SNOWMAN.
7. The Status of the "Country Doctor." HARRY ROBERTS.

1.—Addison, in his lecture on the topographical anatomy of the abdominal viscera, goes carefully into the position and relations of each organ and presents several excellent illustrations. [J.H.G.]

2.—Yeo delivered a lecture on the treatment of

tuberculous peritonitis at the Medical Graduates' College and Polyclinic, on December 19, 1900. The author states that it has been shown that tuberculous peritonitis may be a primary as well as a secondary condition; when primary, the tubercle bacilli, as a rule, gain entrance into the intestinal canal, from infected meat and infected milk; the bacilli pass through the walls of the intestine without producing a lesion, and in this way involve the peritoneum. It frequently happens that lesions are first set up in the intestine and the peritoneum involved subsequently. The author reports 4 cases of tuberculous peritonitis; all of these cases were treated with an ointment containing iodine or iodoform, applied freely to the abdominal surface; iodoform, combined with creosote, was also administered internally; all of the cases made a good recovery. [F.J.K.]

3.—Tooth read the opening paper, entitled "Some personal experiences of the epidemic of enteric fever among the troops in South Africa, in the Orange River colony," before the Clinical Society in London, on March 8, 1901. The object of the occasion being to discuss this recent epidemic. The author believes that the epidemic originated in the Modder River camp; the dissemination of the disease was probably largely due to contaminated water supply and atmospheric disturbances. Sand storms are frequent in South Africa, and Tooth states that the sand was distributed broadcast, and therefore contaminated almost every article of food. He also believes that it is reasonable to suppose that the spread of the disease was in part due to flies and to a less extent by personal infection. Almost every precaution was taken to prevent the spread of enteric fever; the carrying out of sanitary laws was very difficult, and sometimes impossible, as these laws are always subservient to the exigencies of warfare. Preventive inoculation was produced with rather favorable results. From a standpoint of treatment, nourishment was given liberally when it could be done safely; digitalis and strychnia were found to be of great value, and alcohol, as a rule, was used sparingly. Headache was controlled by phenacetin, and sometimes antipyrin was administered; insomnia was, as a rule, treated with phenacetin. A solution containing potassium chlorate, glycerin and perchloride of iron was used to cleanse the mouth; potassium chlorate and sodium bicarbonate were given 3 times a day; these drugs seemed to have a favorable action upon keeping the buccal mucous membrane and the tongue moist. [F.J.K.]

4.—Garrod discusses The clinical and pathological relations of the chronic, rheumatic and rheumatoid affections to acute, infective rheumatism. The most important consideration in his article is whether there is any direct relationship between rheumatoid arthritis and acute rheumatism. The author states that rheumatoid arthritis in the majority of instances appears to be a primary malady with characteristic features from the onset. Infrequently the patient suffering from this form of arthritis has previously been affected with acute rheumatism. He concludes the article by saying that from a clinical and pathological standpoint, there is still much room for the accumulation of facts bearing upon rheumatoid arthritis, and for the present we should take an expectant attitude in this matter. [F.J.K.]

5.—Wilcox, in an article entitled "The toxicological detection of arsenic and the influence of selenium on its tests," concludes as follows: That from his experiments he conclusively proves that the poisoning was not due to selenium primarily and to arsenic secondarily. [F.J.K.]

6.—Snowman describes a patient who suffered after childbirth from septic infection. Several years later the patient suffered from septicemia, and only a year subsequent to this attack she had pyemia, from which she again recovered. [J.H.G.]

New York Medical Journal.

March 30, 1901. [Vol. lxxiii, No. 13.]

1. Congenital Dislocation of the Shoulder, with Report of Two Cases of Dislocation Posteriorly. DANIEL W. MARSTON.
2. The Pathology of Intrauterine Death. NEIL MACPHATTER.
3. The Comparative Pathology of the Jews. MORRIS FISHBERG.

4. The Causes and the Significance of the Obstetric Hemorrhages. J. CLIFTON EDGAR.
5. Tropical Dysenteries. STEPHEN M. LONG.
6. A Dressing for Colles' Fracture. CHARLES L. DEMERITT.
7. A Requisite to Increase the Usefulness of Ambulances. FREDERICK GRIFFITH.

1.—In concluding his article, D. W. Marston comes to the following conclusions: 1. It is of the utmost importance to distinguish between cases of **dislocation and true obstetrical paralysis**. 2. The treatment of the former condition is immediate reduction; by manipulation if possible, otherwise, operative. 3. Every infant should be carefully examined at birth, for it is at this time that reduction is easiest performed. 4. From the facts that a fracture of the glenoid cavity was found in three of Dr. Phelps' cases, and that the history of nearly all cases shows difficult labor, I am led to believe that these cases are not of paralytic origin, or due to nondevelopment, as affirmed by Scudder, but are due to traction made in the axilla by the finger or vectis, or to the arm being caught in some unusual position and dislocated by the contraction of the uterus. Paralysis may be coincident, but it cannot be a primary factor in causing dislocation posteriorly. 5. The prognosis of the operative treatment is excellent. The earlier the operation the more hopeful the outlook. 6. Like congenital dislocation of the hip, these cases of the shoulder are little benefited by mechanical treatment. In connection with the description of the operation here advocated for this deformity, he recommends the new excavator of Dijon, which will be found almost indispensable in the process of cleaning out the glenoid cavity for the reception of the head of the humerus. It is also of value in the open operation for the reduction of congenital dislocation of the hip. The instrument is made in three sizes, and consists of a cylindrical steel tube, conical at one end, furnished with cutting edges like the old-time pot auger used by carpenters. These instruments leave the glenoid cavity with perfectly smooth and regular edges. [M.R.D.]

2.—Will be abstracted when completed.

4.—J. Clifton Elgar divides **obstetric metrorrhagia** into three classes: 1. The metrorrhagia of pregnancy or antepartum hemorrhages. 2. The metrorrhagia of labor or intrapartum hemorrhages. 3. Puerperal metrorrhagia proper, or secondary postpartum hemorrhages. He believes that the most frequently occurring antepartum hemorrhages are indicative of bleeding due to a sudden or inevitable abortion caused by a partial separation of the fetal structures before complete formation of the placenta. Other conditions causing antepartum hemorrhages such as placenta previa, premature separation of a normally located placenta (accidental hemorrhage), ectopic gestation, rupture of the uterus, and menstruation occurring during pregnancy, are discussed, as well as the causes giving rise to each of these conditions. The causes and significance of intrapartum and postpartum hemorrhages are also described. [M.R.D.]

5.—Stephen M. Long believes that **dysentery** should be more thoroughly investigated by the profession living outside of the territories where it is prevalent. He mentions the futility of any treatment devised up to the present time for fulminating catarrhal dysentery. The second type discussed is the simple, acute dysentery starting as a diarrhea and frequently associated with malaria. After discussing the third type generally called the amebic one, and subdivided into the amebic, the trichomonadic, the cercomonadic, and the mixed forms, chronic dysentery as well as the gangrenous and diphtheric forms are considered. The author states that the sequelae of the disease as met with in the Philippine Islands are the following: (1) Its chronicity; (2) chronic gastritis and indigestion; (3) obstinate constipation; (4) paralysis (partial) of the large intestines, due either to obliteration of the glands and lack of secretion or to lack of innervation and blood-supply; (5) anemia, from lack of assimilation of food; (6) the association with it of malarial fever; (7) typhoid fever; (8) neuritis; (9) atrophic cirrhosis of the liver; (10) chronic parenchymatous nephritis; (11) abscess of the liver; (12) metastatic abscesses of other organs, as of the lungs and kidneys; (13) inanition; (14) toxemia; (15) dilatation of the stomach and intestines. He emphasizes the necessity of cleanliness as a prophylactic measure and the avoidance of anything as he terms it "which has not seen the baptism of fire." He does not believe in the employment of alcoholic

drinks as prophylaxis against dysentery, but believes that blackberry brandy, sherry or claret judiciously and cautiously used in the chronic stages, are of value. Sulphate of magnesium, calomel, pecacuanha, opium and bismuth subnitrate are each discussed as to their respective value. Enemata, composed of various drugs that are described individually are extremely valuable when medicines taken per os prove futile. Abdominal massage, turpentine stupes and hot fomentations should also be taken into consideration. [M.R.D.]

6.—C. L. DeMeritt describes a **dressing for Colles' fracture**, consisting of a thin piece of board previously marked out in the desired shape. The ulnar side of the distal end is rounded off, thus permitting the hand to turn in the desired direction. A rounded piece of board with its convex surface above fills out the hollow in the hand. The upper surface of the splint is padded and covered with a roller bandage. [M.R.D.]

Medical Record.

March 30, 1901. [Vol. 59, No. 13.]

1. Some Fallacies of Therapeutics. GEORGE L. PEABODY.
2. Ionization in its Physiological and Pathological Duration. MARTIN H. FISHER.
3. Creosote in Pneumonia; A Résumé. I. L. VAN ZANDT.
4. Orchid Culture in its Relation to a New, Improved, and Completely Effective Method of Disinfection. J. M. W. KITCHEN.

1.—George L. Peabody contributes a suggestive article upon some **fallacies of therapeutics**. He calls attention to that class of mixtures known as "tonics" and "bitters" which are largely consumed by the laity. He has found these very generally to contain a large percentage of alcohol. Almost all of these compounds are sold as being nonalcoholic. The writer believes that in a vast majority of cases in which bitter substances actually do increase the appetite this is due to the fact that the mixture contains alcohol. He states the **boric acid** is another drug which furnishes an illustration of the authority of tradition and the consequent propagation of error. He believes that the disinfecting power of boric acid is so trifling that for practical purposes in this application it must be disregarded entirely. Neither is it to be considered as quite harmless. The use of **tannic acid** is another agent which may be considered of doubtful value. He believes that there is no warrant for the very convenient opinion that after its absorption it can produce **styptic or hemostatic** effects upon remote organs. **Ergot** is known to produce a primary fall of blood-pressure, which is followed almost at once by an enormous and persistent rise of pressure in the arteries. There is no proof that ergot causes any contraction of pulmonary vessels, and it is known to cause a rise in pressure in the pulmonary artery, yet in spite of these facts it is recommended to arrest pulmonary hemorrhage by some authors. **Lithium** is a drug in regard to which much false impression exists. It is practically valueless as a solvent in gout, even when given in reasonably large amounts, and it is especially likely to disorder digestion. Speaking of arsenic, the author mentions the fallacy that a toxic dose which causes death, must necessarily act as a preservative of the body. **Calomel**, he says, is still given to stimulate the liver, whereas experiment has long since proved it to be an **hepatic sedative**. It is at the same time a **cholagogue**, and so is any laxative which acts upon the upper part of the small intestine, and thus causes a discharge of bile that might otherwise be reabsorbed. His conclusions regarding the usefulness of the **iodids** are that except in syphilitic disease they have no power of removing hyperplastic connective tissue or absorbing exudation. He does not believe that it is of any value in chronic lead poisoning. This writer also believes that the sphere of usefulness of **oxygen inhalation** under ordinary oxygen pressure is really very limited. [T.L.C.]

2.—Martin H. Fischer discusses the subject of **ionization in its physiological and pathological relations**. The properties of the aqueous solutions of electrolytes seem to be well explained by the assumption that in these solutions the dissolved substances are split up into ions,

and the properties of the solution are due to the properties of the ions contained in them. For example, HCl dissociates into H-ions and Cl-ions and NaCl disassociates N-ions and Cl-ions. These solutions are the same in so far as they contain Cl-ions and different because one contains H-ions and the other Na-ions. These differences determine the differences in the properties of the two solutions. The physiological action of any substance is due to its chemical character. The chemical character of the solution of an electrolyte is due to the properties of its ions plus the properties of its undissociated molecules. The poisonous properties of a dilute solution are due to the ions they contain, and if at the particular concentration under consideration, toxic ions of only one kind are present, the behavior of the solution is to be attributed to those ions. The change in the irritability of the gastrocnemius muscle of the frog and the amount of water absorbed by it may be taken as an index of the toxicity of the solution of an electrolyte in which the muscle was immersed. The increase in the weight of the muscle is due to an absorption of water, explainable on the ground that the H-ions of the acids or the Oh-ions of the alkalies have a fermented action, which causes hydrolytic splittings in the muscles and an increase in its osmotic pressure. The taste of the solution of an electrolyte is dependent upon the ions contained in it. This theory of **ionization**, which the author presents in a comprehensive and scientific manner, offers, he believes, a new field for investigation in the realm of medicine. He has endeavored to show that in dealing with the action of dilute solution of inorganic substances we are dealing with the action of their constituent ions, and this fact should be borne in mind when we consider physiological, pathological, and pharmacological problems which involve the presence of inorganic substances. [T.L.C.]

3.—I. L. Van Zandt presents a résumé of the **treatment of pneumonia by creosote**. He believes that it cuts short the disease in the most remarkable manner, and that it causes complete resolution of the diseased focus, so that the sequelae are less likely to follow. Furthermore, it is his opinion that the sputum and excreta are voided disinfected. [T.L.C.]

4.—J. M. W. Kitchen contributes a paper upon orchid culture in its relation to a new, improved and complete **method of disinfection**. The author in the course of his experience of raising orchids was met by the difficulty of destroying the insects which interfered with the growth of his plants. He has found that the **formaldehyde** is the most valuable agent at our command. He believes that a number of small generators placed in the several parts of a room are more effective than one large apparatus. [T.L.C.]

Medical News.

March 30, 1901. [Vol. lxxviii, No. 13.]

1. Report of the Committee of the Medical Board of Bellevue Hospital, Appointed January 2, 1901, to Investigate and Report upon Questions Relating to the General Administration of the Hospital.
2. Vaccination, Clinically Considered. FRANK S. FIELDER
3. The Method of Preparation of Vaccine Virus in the Vaccine Laboratory of the New York City Health Department. J. H. HUDDLESTON.

2.—Fielder, in his article on **Vaccination**, emphasizes the following points: 1. Complete natural immunity to vaccination is practically unknown. 2. In primary cases, delayed vesiculation, raspberry excrescence, and abortive course, mean poor virus. 3. Among the complications, there is now no danger of transmitting syphilis or tuberculosis, and other infectious diseases. 4. During the second week of vaccinia, a large painful areola may be considered normal if it be bright red, and if the vesicle be of typical appearance. If the vesicle be irregular, filled with greenish pus, and the areola be of a dark livid, purplish hue, the case is one of mixed infection. 5. Generalized vaccinia, aside from cases in which the eruption is spread by autoinoculation, is rare. Cases of doubtful diagnosis may be tested by the inoculation of lymph from one of the vesicles into another subject. If it be true generalized vaccinia, a localized pock will develop in the inoculated person. 6. The destruction of the vac-

cine vesicle does not interfere with the immunity conferred by the vaccination. 7. Immunity is acquired about the time the areola is at its height—8 to 10 days after vaccination. If smallpox appears at this time it will be mild. If the eruption appears before the vaccination has reached the areolar stage, the disease will not be much modified by the vaccination. 8. Vaccination of the pregnant woman does not protect her child. 9. The fetus in utero may have smallpox, if the mother has it, and may be born with an active rash or with healed scars. A child born while the mother has smallpox is not only not protected, but has been exposed in utero, and will probably develop the disease before there is time to secure protection by vaccination. 10. The duration of immunity to smallpox which is conferred by vaccination is extremely variable, and in the presence of an epidemic, the fact of recent successful vaccination is only presumptive evidence of immunity. Of persons successfully vaccinated within 5 years, very few will contract the disease; but some will, though they will probably have varioloid instead of severe smallpox. 11. The duration of immunity to revaccination which is conferred by vaccination is also extremely variable, and is probably short (two years or under) in a larger proportion of cases than has been supposed. 12. The protective power of vaccination is in direct proportion to its excellence and completeness as shown by the number and quality of the resulting scars. Of the two elements which enter into this protective value, quality of scars is more important than number. 13. While the quality of a scar is a fair indication of its protective power against smallpox, it is an untrustworthy guide in deciding whether the individual is susceptible to revaccination. 14. A person who is immune to smallpox can often be successfully revaccinated. 15. Revaccination protects against smallpox as fully as an attack of the disease protects against a subsequent attack. 16. A person who has been successfully revaccinated is much less likely to contract or to die of smallpox than a person who has been vaccinated only once. The more successful vaccinations one has had at different times, the more certain is his immunity, and the better his chance of recovery if he does contract the disease. 17. Revaccination, therefore, should be considered as important as primary vaccination, and should be just as systematically practised. 18. Primary vaccination should be performed in infancy, revaccination at school age. In the presence of an epidemic, however, revaccination should be performed even though the primary vaccination was of comparatively recent date. 19. The eruption in revaccination is more likely to follow the type of vaccinoid than that of typical vaccinia. 20. Vaccinoid protects if the virus used is of high grade sufficiency. If the virus is poor, only partial immunity is conferred. 21. All vaccine virus should be subjected to rigid physiological tests before issuance. It should be retested monthly, so long as it is on sale. The virus from each animal should be kept by itself and numbered. It should be known by this number when issued so that it can be called in if retests show that its efficiency has expired. 22. Vaccination should be performed under aseptic precautions. 23. It is not sufficient merely to smear the virus upon the scarified areas. It must be thoroughly rubbed or scratched or pricked in. 24. Vaccination shields often do more harm than good. 25. Cases of infected vaccination should be cared for by the physician and not by the mother. 26. Remember that the destruction of the vesicle does not impair the protective power of vaccination, and in signs of mixed infection appear, open the vesicle, cleanse the wound and treat it upon general surgical principles.

1. The Embryological Basis of Pathology. CHARLES SEDGWICK MINOT.
2. A New Method of Treating Fractures. LEONARD F. HATCH.

1.—The ovum is a cell every part of the protoplasm of which is to be regarded as potentially capable of producing any or all of the tissues of the adult. Differentiation in cells resulting from the segmentation of the ovum acts as a progressive restriction of further development. Each successive

stage of differentiation puts a narrower limitation upon the possibilities of further advance. Applied to pathology this law means that the range of possible pathologic changes is determined not merely by the nature or kind, but also by the stage or degree of the previous differentiation of the tissue. The eggs of all animals pass through two well marked phases of development. During the earlier and much shorter phase, the nuclei are multiplying rapidly, while the cytoplasm is growing but little, if at all. During the second and longer period of development, the multiplication of nuclei lags behind the growth of the cytoplasm, which no longer multiplies; the increase is gradual and often shows itself through successive generations of cells. Of the first method of protoplasmic growth, embryonic bloodcells offer a good illustration; of the second, the neuroblasts or young nerve cells afford a striking example. Now cells of the embryonic type show little if any capacity for differentiation, and the increase of the cytoplasm in the single cell is, so far as we can judge, a necessary preliminary step to cell differentiation. The embryonic cells have yet another characteristic of basal significance; they are capable of rapid multiplication. Hence, we conclude, that the growth of the cytoplasm impedes the multiplication of cells, and, therefore, ultimately retards the growth of the body as a whole, while on the other hand it favors differentiation. Accordingly, the growth of cells and their differentiation are essentially antagonistic processes, which are necessarily more or less mutually exclusive. We should conceive of differentiation as a change in the intimate and essential structure of the individual cell, more specifically of its cytoplasm, and perhaps of its nucleus also. It seems probable that the cells of the germ layers are at first quite indifferent, so that if it were possible to graft a young mesodermic cell on to the ectoderm or endoderm, it would become a true ectodermic or endodermic cell. But, in the embryo, each germ layer has its definite, specific value. It is more than probable that all pathologic tissues are as strictly governed by the law of the specific value of germ layers as are the normal tissues. There are 2 distinct types of cell differentiation, for both of which types the starting point is the undifferentiated embryonic cell. In one type we find that as the cells proliferate a portion of them only undergoes differentiation; and another portion remains more or less undifferentiated and retains more or less fully the power of continued proliferation. The second type is characterized by its inclusion of all the cells. Differentiation is a slowly progressive and wholly gradual change in the cell, and we must look upon each step in the process of differentiation as establishing narrower limits for future changes. So in the mesenchyma, after the embryonic cells have changed and large numbers of them have become connective tissue cells, these last still are capable of various further differentiation, and may, therefore, be said to have been arrested in their development at a stage of partial differentiation. This quality of the connective tissue cells is, from the pathologic standpoint, one of the most important facts known to us concerning the structure of the body. The changes that succeed differentiation are destructive and fall into 3 main groups: (1) Changes of direct cell-death; (2) necrobiosis, or indirect cell-death, preceded by changes in cell structure; and (3) hypertrophic degeneration, or indirect cell-death, preceded by growth and structural change of the cell. Necrobiosis and hypertrophic degeneration are normal processes that invariably occur in the normal body and play, in many cases, important roles in the life history of the individual. For example, the thymus and the fetal kidney first attain their full differentiation; their elements die off during the next phase, and finally are resorbed, the greater part of the organ disappearing. In the same category of change belong the histories of the senile ovary and testis. Cell-death on a large scale is a common phenomenon of the tissues. Degeneration, in the stricter sense of an antemortem hypertrophic change of cell structure, is also of widespread occurrence in the healthy body. The various kinds of changes in dying cells, with which the pathologist is most familiar, recur in healthy tissues. Granulation of the bodies of the cartilage cells and of the notochord cells may be observed to precede their resorption. Hyaline transformation is conspicuous in the decidua reflexa. Imbibition or cellular edema occurs in the epidermis of the lips, in the cells of the uterine glands during pregnancy, after they have detached themselves from the gland walls, and in the endothelium

of the placental bloodvessels of the rabbit. Desiccation is the usual accompaniment of cornification. Plasmatorsis is seen in the cells of the secreting milk gland, and also, as an unpublished research of Minot's indicates, to the cells of the secreting glands of the cervix uteri. Karyolysis is, according to present probabilities, the method by which nucleated red bloodcells are converted into nonnucleated blood-corpuscles. Karyorhexis, or the fragmentation of the nucleus, occurs in the cells of the disappearing follicles of the ovary. The sloughing off of cells is one of the most familiar phenomena. On the other hand, cells without access to the external world must be got rid of by resorption, which seems to take place either with or without the cooperation of leukocytes. In the latter case we must, for lack of a better hypothesis, attribute the resorption to chemical means. The author proposes the new term, "cytomorphosis," to designate comprehensively all the structural alterations which cells, or successive generations of cells, may undergo from the earliest undifferentiated stage to their final destruction. This review of normal **embryologic conditions** furnishes us with 3 general conceptions that are valuable for their **pathologic applications**, namely: (1) That each germ layer has a specific and exclusive share in the production of tissues; (2) that undifferentiated cells, characterized by having only a small amount of unspecialized protoplasm, exist not only in the embryo, but also throughout life in certain parts of all 3 germ layers; and (3) that differentiated cells, characterized by having a larger amount of specialized protoplasm, form most of the organs of the adult, and are incapable of undergoing any new unlike differentiation, though they are still capable of completing their cytomorphosis, by necrobiosis or degeneration. We must apply these conceptions as rigidly to pathologic as to normal development. From this viewpoint epitheliomata should be studied in relation to their layership, and it is reasonable to expect that they will be found to have very distinctive characteristics, according to the germ layer from which they take origin, for the layership of a tissue governs the normal differentiation and probably, therefore, the abnormal also. The author especially urges the study of the layership of the various carcinomata. Can we safely assume that there is only one kind of carcinoma? May it not well be that ectodermal, mesothelial and endodermal carcinomata are separate kinds? Undifferentiated cells have the power of multiplication in a high degree, and they have the possibilities of increasing their size and of undergoing further differentiation, and their occurrence in the adult is of the utmost pathologic significance. Such cells exist in 4 important parts: (1) In the basal layer of the epidermis and in corresponding portions of the epidermal appendages; (2) in the adult mesenchyma or connective tissue; (3) in many parts of the adult mesothelium, especially of the epithelia of the genitourinary tracts; and (4) in the endodermal epithelium of the gastrointestinal tract. It is significant that it is precisely from these parts that the development of many rapidly growing tumors takes place, and it is further significant that the least differentiated or specialized of all, namely, the mesenchymal cells, are the ones that produce the greatest variety of tumors. The mesenchyma still exhibits, by the formation of its characteristic tumors in the adult, its embryonic capacity to transform itself in varied ways. Minot would, from the embryologic standpoint, classify new formations into two main groups: (1) Those with marked cytomorphosis, or change in cell structure, as, for example, myoma, lipoma, and chondroma; and (2) those without cytomorphosis, the cells of the new growth resembling those of the parent tissue, as, for example, angioma and glioma. Members of the first group have been termed heteroplasmic; members of the second group have been termed homoplasmic. Accepting these terms, we may say that tumors are either heteroplasmic or homoplasmic. It is probable that highly differentiated cells, such as the nerve cells or the neurons, the liver cells, and the striated muscles, cannot produce tumors. The author concludes (1) that pathologic differentiation in its essential features is identical with the process of normal differentiation; (2) that the character of a tumor depends primarily upon the layership of the cells producing it; (3) that normal differentiation impedes and limits the formation of tumors, precisely as it does of further normal structures, so that tumors arise most readily from undifferentiated tissues and may then be heteroplasmic; arise less readily from differentiated tissues and are then always homo-

plastic; and arise unready or not at all from the most highly specialized tissues. Probably all pathologic necrobiosis and degeneration of cells are essentially identical with normal processes and are pathologic, owing to the abnormality of their occurrence in time and site. [J.M.S.]

2.—Hatch reports a new method for the treatment of fractures, based on modern surgery. The principle is to convert all compound fractures into simple ones, and to operate on simple fractures, making them compound, and then make them simple. The technic of the operation is the same for simple and compound fractures, with this exception, that in simple fracture there is a point of selection for the incision, while in a compound fracture the wound is simply enlarged. There must be the most perfect antiseptic preparation. The site of operation must be shaved and then scrubbed thoroughly with soap and water, bichlorid solution, and permanganate and oxalic acid solutions; all other parts of the patient must be carefully covered with sterile sheets and towels. Hold the extremity in a vertical position for a few minutes, then apply a rubber constrictor. Fit a sterile posterior and anterior splint of any suitable material. The points of selection for incision are for the tibia along the crest, for the femur along the outer side of the thigh, for the radius behind the supinator longus, for the ulna along the ulnar side of the arm where the bone is most superficial, for the humerus along the outer side of the arm. A good free incision should be made, as it is important to have plenty of room, and the size of the incision does not complicate the case. Wash out thoroughly all clots and debris, removing all shreds of soft tissue and loose pieces of bone. If any sharp points of bone prevent perfect coaptation remove them. Remove rubber band. Tie all bleeding points, and be sure that the wound is dry. If in a case of a compound fracture the periosteum is stripped up, carefully replace it. Secure perfect coaptation. Apply one of the splints before closing the wound, to make sure of holding the fragments in place. Close the wound with catgut sutures without drainage, and lay a thin pad of iodoform gauze over the wound; apply the second splint and bandage quite firmly, as there will not be any swelling like that which occurs after a fracture treated in the usual manner. Remove dressings on the seventh or eighth day and apply plaster cast or ambulatory splint, according to the requirements of the case. With this method it is safe to discontinue splints at least one week earlier than in fractures treated by former methods. With the advance made in modern surgery, where we do not hesitate to enter the abdominal or cranial cavities, in some cases even, simply to establish a diagnosis, we surely should not be deterred from operating on fractures by fear of sepsis, and it certainly is unscientific to adopt a blind way when a better presents. The method would be warranted if it did nothing more than to relieve the pain and swelling, which it certainly does. It shortens the repair process at least one week. It reduces the chances of deformity and nonunion to a minimum. [J.M.S.]

9. Open Treatment of Suppuration of the Knee-Joint. W. J. MAYO.
10. Quantitative Tests for Proteolysis. A. L. BENEDICT.
11. The Rule of Rapid Operating and the Importance of Saving Time in Surgical Operations. JOHN S. MILLER.
12. Venereal Disease as a Social Problem. W. C. GATES.

13. Circumcision in Restricting the Spread of Syphilis. HOWARD N. MOYER.
14. Report of Special Committee of the Section on State Medicine of the American Medical Association, Appointed to Inquire Whether and When the Gonorrheic may be Permitted to Marry, and Whether the Matter is a Proper one for Regulation by Statute.
15. Purulent Otitis: Its Treatment and Prevention by the Family Physician. H. GRADLE.

1.—Bulkley reviews the important recent advances in dermatology which are of service to the general practitioner from the standpoint of diagnosis, pathology and therapeutics. [F.J.K.]

2.—Dalton holds that hyperacidity of the contents of the duodenum, due to the hyperacid condition of the stomach, produces derangement of physiologic metabolism, and is the starting-point of nearly all the diseases of the skin, except the contagious exanthemata. [F.J.K.]

3.—Gottheil reports two cases of acute suppurative folliculitis of the scalp. One of the cases is described in detail; this case terminated in recovery and the affected parts returned to a normal condition. The author does not venture to explain the causes which give rise to this acute suppurative process.

4.—Eads reports a number of operations for injuries to the median and ulnar nerves with a good result in each case. For nerve suture Eads prefers silk rather than catgut, or else chromicized catgut. In suturing a nerve care should be taken that it is so placed as not to be caught and pressed upon by cicatrices. [J.H.G.]

5.—Salmon gives a detailed account of the pathological conditions found in meat inspection. He mentions the various statistics in reference to the number of carcasses that were condemned and the reasons for such action. Reference is made in regard to the limitations of authority of the inspectors. Finally, he emphasizes the fact that no public work can be carried to the highest degree of efficiency unless its object and value are understood by the people of the country. [F.J.K.]

6.—Mathews describes a very severe case of prolapse of the rectum in an adult, in which he obtained an excellent result after opening the abdomen and suturing the bowel to the abdominal wall. When he performed this operation he was not aware that it had ever been done by any other surgeon. He thinks that coloproctia in case of prolapse of the rectum of the second or third degree is preferable to other methods of operation for this condition, and that it is accompanied by less danger. In suturing the bowel to the abdominal wall he prefers a continuous suture. [J.H.G.]

7.—Inglis writes upon the sanitary conditions of Peking, and concludes by saying that before China is admitted to the society of enlightened nations, she should make her capital less dangerous as a place of residence, by instituting proper sanitary measures, thereby checking the prevalence of those diseases which are due to the products of filth. [F.J.K.]

8.—In an article on thyroid tissue in the larynx and trachea, Freer gives an account of the symptoms of the condition, the theories regarding the entrance of a thyroid tissue into the larynx and trachea, the prognosis, the diagnosis and the treatment. In the article is included a report of a case, and mention is also made that nine other cases have previously been recorded.

9.—Mayo strongly urges the open treatment for severe suppurations involving the knee-joint, maintaining that he has seen limbs saved by this method of treatment where amputation was thought to be necessary in order to save life. The incision extends across the front of the knee-joint and gives most satisfactory drainage. Ankylosis nearly always follows. [J.H.G.]

10.—Benedict discusses the quantitative test for proteolysis, and formulates the following conclusions (so far as the test breakfast is concerned, the stomach being evacuated after 60 and 90 minutes): 1. In individuals who are normal, the proportions of the three stages of proteids do not vary materially during the third half-hour of digestion, nor according to moderate variations in other respects. 2. A mere trace of syntonin, not exceeding $\frac{3}{100}$ cc. in 10 cc. of filtered chyme, is most typically represented. 3. Albumose (by ammonium sulphate) is most typically represented by

cc. in 10 cc. 4. Most typically peptone is represented by $\frac{1}{100}$ to $\frac{2}{100}$ cc. in 10 cc., but there may be variation between $\frac{1}{100}$ and $\frac{2}{100}$. [F.J.K.]

14.—Tuckerman submits a "Report of the Special Committee of the Section on State Medicine, of the American Medical Association, appointed to inquire whether and when the gonorrheic may be permitted to marry, and whether the matter is a proper one for regulation by statute." Various questions pertaining to this subject were submitted to prominent gynecologists and genitourinary specialists. Their answers are given in the report; no final conclusions are, however, drawn. [F.J.K.]

15.—Gradle urges the importance upon the general practitioner of early incision of the drum in purulent otitis. He condemns most strongly the use of the popular remedy for earache, such as opium and sweet oil and camphorated oil. The only local application which can be of any service is a 10 to 12% solution of carbolic acid in glycerin, and opium internally is the only remedy which will control the pain. The improper use of the nasal douche Gradle thinks is a prevalent cause of otitis. [J.H.G.]

Journal of Experimental Medicine.

January 15, 1901. [Vol. v, No. 3.]

1. The Superficial Glands of the Esophagus. ALBION WALTER HEWLETT.
2. False Diverticula of the Intestine. MARTIN H. FISCHER.
3. Some Theoretical Considerations Upon the Nature of Agglutinins Together with Further Observations upon *Bacillus typhi abdominalis*, *Bacillus enteritidis*, *Bacillus coli communis*, *Bacillus lactis aerogenes*, and some other Bacilli of Allied Character. HERBERT E. DURHAM.
4. Report of a Laboratory Epizootic among Guineapigs, Associated with Gaseous Emphysema of the Liver, Spleen, and Kidneys, due to *Bacillus mucosus capsulatus*. R. G. PERKINS.
5. On the Relation of Chronic Interstitial Pancreatitis to the Islands of Langerhans and to Diabetes Mellitus. EUGENE L. OPIE.

1.—The esophageal glands, which have long been known, are situated in the submucous tissue of the esophagus. Hewlett describes a second group of glands situated entirely within the mucous membrane of the **esophagus**, above the muscularis mucosae, which were originally described by Rüdinger, in 1879. These glands are of the tubercumose type and are found in small circumscribed areas in the upper third and the lower third of the tube. They produce oval defects in the mucous membrane that may readily be mistaken for ulcers. The **superficial glands** present many cyst-like dilations. The acini are lined by low columnar cells and by cells that are identical with the parietal cells in the cardiac glands of the stomach. The morphologic significance of the glands is not clear. The pathologic relations of the glands are of interest on account of the possibility that they may act as a nidus for the development of a pulsion diverticulum of the esophagus. They may be a source of origin of esophageal cysts and they may give rise to carcinomata. [J.M.S.]

2.—A false diverticulum of the intestines is a hernia of the mucosa and submucosa through the muscular wall so that the wall of the pouch is formed of the two layers forming the protrusion covered by the serous coat of the bowel. Fischer describes a case of single diverticulum of the jejunum; a case of multiple diverticula of the ileum; a case of diverticula of the rectum, omega loop, and descending colon, and a case of diverticulum of the appendix. These diverticula are usually found in the position of a dilated bloodvessel and extend in the course of this bloodvessel either between the layers of the mesentery or on one side of that structure. The force producing the outpouching of the mucous membrane apparently comes from within the bowel and, as the hernia passes through the muscular coat, that tissue is broken and then crowded to either side. Doubtless the chronic passive congestion of the viscera due to hypertrophy and dilation of the heart and arteriosclerosis is an important factor in the causation of the diverticula. The walls of the diverticula often present inflammatory changes. The

diverticulum of the appendix described in the paper occurred on the side opposite to the mesoappendix. Its wall was composed of serosa only, so that it is possible that the condition was originally one of true diverticulum produced by traction of an old adhesion and that the accumulation and stagnation of feces in the pouch caused pressure atrophy of the mucosa and muscularis in the wall of the sac. [J.M.S.]

3.—Further experience with the differential actions of serums of treated animals leads Durham to confirm the conclusion that, so far as bacteriolytic and agglutinating actions are concerned, the word specific is inapplicable and special would be a better term to employ. It has been found that the serum reactions are not uniform within the species *vibrio cholerae asiaticae*. From this and other observations it would seem as though the serum test could not be considered a final criterion for the diagnosis of species. The author's experience is contrary to that of Baumgarten concerning the power of the serum of rabbits to agglutinate colon bacilli. He attributes Baumgarten's results to the fact that cultures in broth made with muscle sugar were used. Such broths when mixed with fresh broth or serum may give precipitation of proteid matters that produce an apparent agglutination. The author believes that the bacillary agglutination process is not due purely to an entanglement of the bacilli in coagula formed in the free fluid. The microscopic observation of bacilli mixed with very dilute special sera is most suggestive of some alteration of the surfaces of the bacilli in the direction of increased stickiness. It may be that this surface alteration is due to a precipitation or more or less nascent precipitation upon the surfaces of the individual susceptible bacilli; such bacilli as are secreting more of appropriate substances will be more susceptible to the action of the serum and become more profoundly affected. It is always a striking phenomenon that all the bacilli are not equally influenced in a given dilute mixture. In order to explain the perplexing partial and mutual reactions of agglutinating sera upon different races or groups of bacteria, the author supposes that a given **agglutinin** is not a single substance, but a complex one, while the bacillary components that are capable of giving rise to the formation of agglutinins are also variable and not produced in the same amount in all species or in all races. It is possible that the agglutinin producing substances and the agglutinin overlap in organisms, such as *bacillus typhosus* and *bacillus enteritidis*. Moreover, any given race does not necessarily produce the same quantities of the different constituents at different times, and hence the variations of agglutinability, virulence, etc. It is further supposed that the bacteriolytic, inhibitory, and protective or preventive substances have a similarly complex constitution, the amount of each unit being to some degree independent of the others, although all the substances tend to be grouped together more or less dependently. From numerous experiments, it seems that the most satisfactory method of producing clumping sera is to give considerable quantities of killed bacilli by the intraperitoneal route. It is possible to get moderate potency by giving sterile filtrates of cultures and to induce some power by giving killed cultures by the mouth. These facts seem further evidence that agglutination is no reaction of infection. Agar cultures should be used because broth is unsuitable on account of the precipitation of the peptone from the broth by the serum of the animals, as shown by Myers. The effect of a given injection probably reaches its height, when killed bacilli are given, in about 10 days or 2 weeks. The author concludes that the **clumping reaction is of little value for differentiating and classifying these bacilli** in a satisfactory manner. It appears that we can only find whether the products of bacilli that are capable of giving rise to agglutinins are the same in 2 or more cases. Even then, although these may be the same substances qualitatively, these may not necessarily be present quantitatively to the same extent. Again, by taking the same race of bacilli and its own serum, we find that the susceptibility of cultures made at different times is not necessarily the same. A classification of the types that have been studied follows, with a consideration of the ordinary characteristics, and an account of the media that may be useful for further work. [J.M.S.]

4.—Perkins describes an **epidemic of epizootic** that occurred among his laboratory guineapigs. The fatal cases

terminated with coma and muscular twitchings in from 12 to 48 hours after the onset of the disease. Two animals recovered after infection. Among the fatal cases 65% presented a well-marked peritonitis of the seropurulent type. The liver in every case showed marked congestion and cloudy swelling, and in 60% there was a general gaseous **emphysema of the spleen**. In 39% of the animals a similar condition of the spleen was associated with the **emphysema of the liver**; while the spleen was markedly congested in all cases. The kidneys and the adrenals showed congestion and cloudy swelling only. The gastrointestinal tract contained gas, but no lesion could be demonstrated. With two exceptions each autopsy gave pure cultures of a pleomorphic non-motile organism, most frequently occurring in the form of a short bacillus with rounded ends. There was no capsule. The organism stained readily with the aniline dyes, and decolorized rapidly with Gram's stain. The organism was not like the bacillus *areogenes capsulatus*, although it undoubtedly belongs in the ***bacillus mucosus capsulatus*** group. The 2 animals that recovered possessed a high degree of immunity to the organism causing the disease. [J.M.S.]

5.—Opie has studied 17 cases of **pancreatitis**. In congenital syphilitic pancreatitis he finds that the development of the glandular acini is retarded but that the **islands of Langerhans** are not affected. These bodies are embedded in the stroma, but they are not invaded by it and they maintain their continuity with the small ducts and acini with which they have a common origin. There are two types of chronic interstitial inflammation: (1) Interlobular pancreatitis and (2) interacinar pancreatitis. In the interlobular variety the inflammatory process is localized chiefly at the periphery of the lobule and implicates the islands of Langerhans only when the sclerotic process has reached a very advanced grade. When pancreatitis has followed obstruction of the ducts, the islands remain unaltered for a long time, although they are embedded in dense scar-like tissue. In the interacinar type the process is diffuse, invading the lobules and separating individual acini. The inflammatory change invades the islands of Langerhans. The author has observed a relationship between the lesions of the islands of Langerhans and the occurrence of diabetes mellitus. In one of 11 cases of interlobular pancreatitis, diabetes of mild intensity occurred. The sclerosis, which in this case followed obstruction of the ducts by calculi, was far advanced and affected the islands of Langerhans. In 2 of 3 cases of interacinar pancreatitis, diabetes was present. The third case was associated with hemochromatosis, which at a later stage is associated with diabetes, the result of pancreatic lesion. In a fourth case of diabetes, hyaline deposit between the capillaries and the parenchymatous cells had so completely altered the islands of Langerhans that they were no longer recognizable. [J.M.S.]

6. Physiological Dilation and the Mitral Sphincter as Factors in Functional and Organic Disturbances of the Heart. MORTON PRINCE.

1.—Burrows, during his service in the department for contagious diseases in the Boston City Hospital collected records of 2,093 cases of **diphtheria**, all of which were treated by **antitoxin**. From these records he has attempted to give a clinical picture of the disease as it has been modified by the antitoxin treatment. There were slightly more females than males. The death-rate decreased with the age of the patient, being 14% of all patients under 15, and 2.85% of patients above that age. The greatest proportion of deaths, 37%, occurred in the first two years; and only 2 occurred in the 127 patients over 30 years of age. As, however, 69 pa-

tients were moribund when admitted, and died within 24 hours, the true death-rate of the disease when properly treated was not over 9%. An interesting factor was the variability in the cases grouped by hundreds according to the order of admission. The death-rate under these circumstances varied from 5 to 19%, showing the extreme inaccuracy of statistics based upon small numbers of cases. In the great majority of cases the membrane showed the ordinary distribution upon both tonsils. In 71 there was diphtheritic membrane in the tonsils, and in a number of others a discharge which suggested nasal infection. Cultures were always taken from the throat and nose. They were positive from both nose and throat in 632 cases. From the nose 159, and from the throat 954. In 228 cases of undoubted diphtheria the cultures were negative. The other organs showed the following alterations in the course of the disease. The heart frequently developed a soft systolic murmur, usually most distinct over the mitral area, but occasionally heard loudest at the base. Irregularity was common, and in a considerable proportion of cases both irregularity and murmurs developed. Cardiac lesions were usually present when the patient entered the hospital, but sometimes did not develop for several days. One-half of the cases gave murmurs, and one-third irregularity. There was usually tachycardia, the pulse ranging from 100 to 200. The proportion of deaths was very much increased when the maximum pulse exceeded 170. Albuminuria was exceedingly rare, and this is, perhaps, the most significant result of the antitoxin treatment. The albumin never exceeded $\frac{1}{4}$ of 1% by weight, and in considerably more than half of the cases was not found. Three hundred and thirty-seven of the 1962 cases had symptoms of laryngeal stenosis; 213 of these required intubation; and 96 died, 37 being moribund when admitted. Three cases subsequently requiring tracheotomy, and all died. Two required tracheotomy, and recovered. It is interesting to note that in both the cases of tracheotomy that recovered the constriction was due not to membrane, but to peritracheal abscesses. Burrows believes that primary tracheotomy is no longer required in diphtheria. Among the other complications were vomiting, middle ear disease, suppuration of the cervical glands, and the post-diphtheritic paralyses. These, however, were not especially common, occurring in only 102 cases. The majority of them occurred during the acute stage of the disease, and many were due to mixed infection. The most striking portion of the paper is the brief section devoted to treatment. Burrows and his colleagues have reached the conclusion, as the result of their extended experience, that the antitoxin is not under any circumstances injurious, and should be given until the symptoms are relieved. The routine treatment, therefore, consisted in the administration of 4,000 units every 4 hours, or in severe cases, every 2 hours. He believes that by this vigorous administration, cases apparently moribund have been saved. He mentions in particular patients that received from 40,000 to 110,000 units in the course of the disease. Comparing the statistics in the hospital before and after the introduction of the antitoxin treatment, he believes that the death-rate has been lowered 33%. The other therapeutic points are the use of alcohol, feeding intubated patients through the esophageal tube, and rectal feeding when the vomiting was annoying. [J.S.]

2.—Howard examined 3 cases of **acute interstitial nephritis**. One was a case of general streptococcus infection, the other 2 without demonstrable microorganisms in the kidneys, although in one of these a large number of streptococci were found in the other organs. The interesting features were the discovery of plasma cells, lymphocytes, and polymorphonuclear leukocytes in the tissues and in the dilated vessels. The plasma cells showed evidence of ameboid activity, and some of them had mitotic nuclei. In addition he found great numbers of typical eosinophilic leukocytes. [J.S.]

3.—Hektoen reports the following cases of **cardiac anomalies**: One in a child recently born, that died of general infection with the *Bacillus mucosus capsulatus*. He found a large defect in the septum between the pulmonary artery and the aorta, consisting of an oval opening about 1.5 cm. in diameter. The ductus arteriosus was patent; the veins were normal. He has collected 10 other cases of this condition. It is interesting that some of these patients lived for a considerable time. They all gave marked evidences of

heart-disease, the physical signs varying from a systolic bruit at the base to both diastolic and systolic murmurs, frequently changing in character. The second sound was accentuated in one case. There was usually hypertrophy of the right ventricle that could sometimes be diagnosed during life. In one or two cases there was cyanosis. The second patient had a curious depression under the base of the anterior aortic valve connecting with the ventricle, through which regurgitation occurred. This is unique, and it is difficult to understand by what freak of embryological development it was caused. [J.S.]

4.—The patient, a man 49 years of age, had had the back of his right hand scratched by the teeth of a cat. He also caressed very frequently his dog which was suffering from mange. A few weeks later he developed a small pustule which broke down, healed, and a crust formed over the opening. Then other pustules appeared, and the condition gradually extended until the whole back of the hand was involved. Cover-glass preparation showed the presence of staphylococci, long streptococci, and a few yeast fungi. Cultures of the yeast plant were obtained on glycerin agar, and a diagnosis of **blastomycetic dermatitis** was made. Mild antiseptic treatment appeared to improve the disease.

5.—Schamberg reports the case of a woman, 39 years of age, who had been inoculated 8 years previously with syphilis. Since then she has had a great number of syphilitic skin lesions which have resisted all forms of anti-syphilitic treatment. Her general health remains good, and she has gained in weight.

6.—Prince, in an article with numerous numbered paragraphs, discusses **functional mitral regurgitation**. He considers that the mitral ring probably dilates and contracts with the dilatation and contraction of the ventricle, and is not rigid as is the aortic ring. The sphincter-like band of muscles around the ring is essential for maintaining its competence. When, however, the tonus of the sphincter is diminished the ring may dilate to such an extent that regurgitation can occur. The work of Roy and Adami has shown that irritation of the various nerves leading to the heart may have great influence upon the size of the organ, and the completeness of the muscular contraction. Prince has observed that in men apparently healthy, who were examined under conditions tending to produce considerable excitement, murmurs not infrequently developed. These murmurs have all the physical characteristics of mitral murmurs. Examination of some of these cases have shown that the heart is considerably increased in size, and it is probable that the murmurs were merely functional in character. He quotes the results of the investigations of various other investigators in support of his views. [J.S.]

6. Stereognosis and Allied Conditions. BURR.
7. Clinical Study of Acute Myocarditis. ROBINSON.

1.—Packard and Le Conte report 2 cases of **cirrhosis of the liver** in which the **operation of stitching the mesentery to the abdominal wall** was performed in order to promote the establishment of a collateral circulation. The first patient, a man of 63, was operated upon only after repeated tapping had failed to relieve the ascites, and the symptoms were rather alarming. After the operation, the patient was very depressed and weak, and he died in 53 days of heart-failure and pulmonary edema. The autopsy confirmed the diagnosis. The second patient, a man of 52, had practically the same indications for operation, but afterward became delirious and died with symptoms of uremia. There was no fever and no signs of infection. The authors give a general discussion of the subject, quoting extensively from the literature. They believe that

the operation may be of benefit in two ways: First, by diminishing the congestion of the liver; secondly, by increasing the vascular supply of the surface cells so that they may undergo compensatory hyperplasia. They regard the ascites, therefore, as due almost exclusively to the portal obstruction. Le Conte gives the following suggestions in regard to the operation. He objects to etherization, preferring chloroform and local anesthesia. A primary incision is made above the umbilicus and a little to the left of the median line, and the liver palpated. A small opening is then made in the median line just above the pubis and the fluid siphoned off through it. The parietal peritoneum over the omentum, liver, and spleen is then rubbed with a gauze sponge, and the surface of those organs is treated in the same way. The omentum is then stitched to the anterior abdominal wall, and the incision closed. Drainage may be made through the larger opening. The abdomen should be encircled with broad adhesive strips. Twenty-two cases have been recorded, giving the following results: Immediate death, 5; ultimate death, 3; unimproved, 3; improved, 2; recovered, 9. As the operation has been chiefly performed upon cases that were otherwise hopeless, and after repeated tapping had failed to make any impression on the peritoneal accumulation of fluid Le Conte regards these results as encouraging, in fact some authors are already urging an early operation. The authors strongly recommend the operation. [J.S.]

2.—A man, 40 years of age, had complained for some months of a sense of fullness in the abdomen, also progressive emaciation and severe cough, with night sweats. He had fever, was anemic, and had a rapid pulse. Tubercle bacilli were found in the sputum, the spleen was enormously enlarged, and the liver moderately so. Repeated examinations of the blood showed progressive diminution in the red blood-cells and a very considerable leukocytosis, at one time exceeding 300,000 whites per ccm., considerable reduction in hemoglobin, and a very large proportion of myelocytes, sometimes amounting to nearly 40%. In the course of the disease the general changes in the white cells were a steady decrease in their number, an increase in the percentage of polymorphonuclear neutrophils and the lymphocytes, and a decrease in the number of myelocytes. During all this period the tubercular process was advancing. The case is reported as one of **tuberculosis associated with splenic myelogenous leukemia**. [J.S.]

3.—Eshner and Weisenberg report the following cases. A man of 39, who had been a heavy drinker, was admitted to the hospital delirious. He developed characteristic symptoms of **typhoid fever**, and on the sixth day after admission, a rose-red eruption appeared that did not disappear upon pressure. The same day he had hematuria and a bluish papular eruption over nearly the whole body, severe hemorrhage from the bowels, and an extravasation of blood in the cornea of the left eye. He died, and at the autopsy, blood was found in the serous cavities. The intestine showed the characteristic ulcers. The second patient, a man of 23, also an alcoholic, gave the characteristic symptoms of typhoid fever. He also developed a peculiar red papular eruption that did not disappear upon pressure. He had symptoms of meningitis; that is, divergent strabismus, retraction of the head, and later Kernig's sign. He became comatose and died. The autopsy showed only the lesions of typhoid fever. [J.S.]

4.—Pepper reports the following interesting cases: A female child, born August 19, remained well until September 14. At this date the abdomen began to enlarge; there was emaciation and diarrhea. The distention was evidently due to an enormous enlargement of the liver. A few days before death there were small hemorrhagic petechiae. At the autopsy the enormously enlarged liver, upon section, was yellowish white in color with a few hemorrhagic areas. The right suprarenal was enlarged, and had the same appearance. Microscopic examinations showed that both the **liver and right adrenal were infiltrated with lymphosarcomatous tissue**. Pepper has been able to collect 5 cases of this nature from the literature, which give the following interesting points of resemblance: Swelling of the abdomen at a very early age, varying from birth to 5 weeks; death a short time afterwards, from 10 days to 16 weeks. The very rapid growth of the liver; the fact that all the cases excepting one were females, and in this one case the sex was not mentioned. The clinical symptoms were, in addition to

distention of the abdomen, moderate wasting, but there was no jaundice nor ascites, nor pigmentation of the skin. The children did not appear to suffer pain. There was no fever and they all nursed well until shortly before death. There was no history nor sign of syphilis. The changes were practically identical in all, nor were any other organs excepting the liver and suprarenal involved. The kidneys were always normal. The disease differs considerably from primary sarcoma of the suprarenal, of which Pepper has collected 46 cases, given in tabulated form. Primary sarcoma of the liver appears to be very doubtful. [J.S.]

5.—DaCosta reports a case of rapidly growing sarcoma of the thigh occurring in a girl of 15 years. This ruptured through the skin, fungated, and bled profusely. Amputation was therefore indicated, and hemorrhage was controlled according to McBurney's method of opening the abdomen and compressing the iliac vein and artery against the psoas muscle. As the anterior portion of the thigh was involved it was necessary to make a long posterior flap. The operation was entirely successful, with the exception of the fact that the weight of the fat caused gaping in the external fourth of the wound. Six weeks later recurrence appeared. Da Costa states that in future cases he would make the posterior flap consist almost exclusively of skin in order to decrease its weight. The growth was a small cell sarcoma. [J.S.]

6.—Burr reports several interesting cases. The first, a man, had received as a boy a fracture of the right parietal bone. Subsequently, although there was no paralysis, he could not locate sensation, and had persistent **stereognosis**. The second patient had tumor of the brain localized in the right parietal region. There was slight hemiparesis. In the right side muscular sense was apparently fair, but the localization sense was greatly impaired. He also had complete stereognosis. The third patient had a fracture of the right parietal bone. Subsequently had impairment in the movements of the left hand, with a good deal of pain when they were moved. There was loss of sensation of position, and partial stereognosis, which apparently was not limited to any particular class of objects. The fourth patient, a man of 52, had hemiparesis of the right side. There was tremor of both arms, ataxia of the right arm, and hypæsthesia. There was some impairment of motion, but complete stereognosis in the right arm, and later some sensory aphasia. The diagnosis was made of tumor in, or near, the left angular gyrus, and this was confirmed at the autopsy. The last patient, a woman of 30, had sluggish movements, and there was complete paralysis of the right side of the face, atrophy of both optic nerves, and complete loss of all sensation in the left arm. Nevertheless, she recognized and correctly named all sorts of objects placed in the left hand. The diagnosis of this case Burr leaves in doubt. Burr believes that stereognosis is produced by disease either of the cortical area for perception or its afferent or efferent tracts. He accepts the cortical sensory area for the recognition of objects by handling them, and calls attention to the analogies between this condition and the various forms of aphasia. He suggests that in the last case, the tactile sensory area is not the same as the cortical area for perception, and that a lesion in the tract uniting them might cause the symptoms. [J.S.]

7.—Robinson discusses the various forms of **inflammation of the heart-muscle**. He speaks of the symptoms of heart-failure that may occur in acute infectious processes, and in which a soft flabby heart is found at the autopsy. He thinks that potassium iodid is less used in such affections than it should be. He also thinks that oxygen, to which a small proportion of nitrogen monoxide has been added should be given continuously. He also makes warm, moist applications to the pericardium, and if necessary small amounts of opium may be given for a soothing effect. Of all cardiac stimulants he is most impressed with the value of coffee and cocoa. After recovery from an acute condition, enlargement of the heart may sometimes occur. [J.S.]

5. Tumor of the Cerebellum in a Boy of Seven Years. S. R. KETCHAM and L. C. PETER.

7. Report of a Case of Diabetes in an Infant. WILLIAM E. YOUNG.

1.—Hamill's article on **hemorrhage into the suprarenal capsule in stillborn children and infants** is concluded by a review of the literature. [J.M.S.]

2.—The diagnosis of adenoids may be made (1) from the symptoms, (2) by means of the rhinal mirror, or (3) by digital exploration of the nasopharynx. The symptoms are often so plain that no one can fail to interpret them correctly. The use of the mirror for posterior rhinoscopy is impossible, as a rule, in children. Digital exploration after a little practice is readily performed and yields the desired information. For one reason or other it may not be desirable at the time to resort to a digital examination. Under such circumstances, reliance may be placed on two symptoms. Either one or the two jointly offer a ready and easy method for a correct diagnosis. 1. The presence of two small lymph nodes, painless and freely movable at the angle of the lower jaw, one on either side. 2. Upon oral examination and inspection, if the size of the tonsils does not obstruct the view, numerous small hypertrophies will be found upon the mucous membrane of the posterior pharynx, now and then, at the level of the soft palate, larger masses are present. In the **treatment** two points must be considered: (1) The removal of the lymphoid hypertrophies constituting the tonsillar ring; and (2) the effects, local and general, of the interference with normal nasal respiration. The earlier the treatment is instituted the greater the success in preventing secondary changes. In case decided symptoms are associated with adenoids, the growth should be removed. This may be accomplished by the finger, forceps or curet. Huber prefers to operate without narcosis. The existence of an acute otitis, bronchitis, or inflammatory process in any part of the respiratory tract is a contraindication to operative interference. Bleeders, or those who have had petechiæ, are best left alone. [J.M.S.]

3.—Donald selected 20 children and the temperature of each was taken twice daily, at about 8.30 A.M. and 6 P.M., for a period of 14 days. During the 14 days in which the tests were conducted, he had 28 collective readings, and out of these 28, 12 readings, or 42%, gave a mean or average temperature of 99° F. or over. The higher readings occurred at the afternoon tests in the majority of cases; 9 of these being recorded in the afternoon, and but 3 in the morning. On five different occasions, or about 18%, the mean temperature on the collective reading showed a higher range in the morning than in the evening of the same day. There was a tendency toward a constant high temperature in about 30% of the cases examined. The children were especially selected from nearly 100 in an asylum on account of their **perfect condition of health**. No one of them was sick at any time during the tests and none of them has developed any illness since. [J.M.S.]

4.—Thomson reports the case of a girl, 9 weeks old, who was suffering from blueness of the face and hands. The child's cyanosis had been noticed by the parents from birth, but, as the patient seemed well in other respects, they had not been concerned about it. The hands, the feet, and the face, especially the lips, were distinctly cyanotic. The pulse was very rapid, 156, and small but regular; the respirations were 36 in the minute. The lungs and the abdominal organs appeared to be normal. The heart's apex beat was very indistinct, and was situated in the fourth left interspace about $\frac{1}{2}$ inch outside the nipple line. No thrill could be felt in any area. There was no increase of the cardiac dulness and no sign of enlargement of the right side of the heart. On auscultation, a loud systolic murmur was heard, which was most marked over the base of the heart, especially to the left of the sternum, but was also audible in the other

areas, in the axilla, and in the interscapular regions. The pulmonary second sound was normal and not accentuated. There was no clubbing of the finger ends. Two months later, only very slight cyanosis of the feet and legs was noticed. The murmur was distinctly less loud, and over the tricuspid area it was quite inaudible. The pulse was 152. Seven years afterward, the child, who had been tolerably well since last examined, was fairly healthy in appearance. She showed no trace of cyanosis and had no clubbing of the fingers. Her pulse was normal in rate and rhythm. While the facts given above are hardly enough to found a sure diagnosis upon, it seems probable to the author that the murmur and other signs of circulatory disturbance in this patient may have been due to a **patent** and perhaps **dilated ductus arteriosus**, while the disappearance of the symptoms points to the closure of the lumen of the vessel. [J.M.S.]

5.—Ketcham and Peter report the case of a boy in whom nystagmus was noticed soon after birth, followed in a few years by a titubating gait, static ataxia, incoordination of the upper extremities, headache, vomiting, and choked disc. The symptoms are clearly those of **tumor of the cerebellum**. [J.M.S.]

6.—Young reports the case of a boy, 6 months old, who commenced to vomit. His stools were green and contained undigested material. At every weighing a loss of several ounces was noted, the child was emaciated, and his skin was very dry and wrinkled. An examination of the urine showed a specific gravity of 1.030, about 5% of sugar, very little albumin, and a few casts. The child died of pneumonia. At autopsy the cortex of the kidneys was grayish-white and indurated. There were marked hyperemia and inflammation of the parenchyma. [J.M.S.]

Journal of Nervous and Mental Disease.

March, 1901. [Vol. xxviii, No. 3.]

1. The Amelioration of Paralysis Agitans and Other Forms of Tremor by Systematic Exercises. JOHN MADISON TAYLOR.
2. A Case with the Symptoms of Cerebrospinal Meningitis, with Intense and General Alteration of the Nerve-Cell Bodies, but with Little Evidence of Inflammation. WILLIAM G. SPILLER.
3. A Case of Muscular Dystrophy. CHARLES GILBERT CHADDOCK.

1.—Taylor is convinced that in this form of tremor, whatsoever the cause, we may hope to obtain fair amelioration of symptoms, and it may be in some instances a cure, by carefully regulated and systematized movements. These should be such as shall reestablish the largest degree of elasticity in the tissues which have suffered contractures. They should always include passive extensions and flexions, followed by active repetitions of these acts. The most important movements to overcome the milder forms of tremor, as the senile form, are slow, full, forcible extensions. An important part of the treatment is the attainment of normal attitudes. Along with this should be continued conscientious efforts on the part of the patient to acquire full thoracic capacity and as much elasticity of the lungs as possible. [T.M.T.]

2.—Spiller reports a case with **symptoms of cerebrospinal meningitis** existing for six days without lesions sufficient to explain them at necropsy. A very slight round-cell infiltration was observed in some parts of the pia and about some of the intramedullary bloodvessels, but the smaller vessels of the pia and anterior and posterior roots were much distended with blood. Numerous small bacilli were found within the nervous tissues. Some authorities think that this same condition is found in cases of amaurotic family idiocy, but Spiller does not agree with them, and reports cellular infiltration in two cases of children of feeble mental development, one the above reported case and the other of internal hemorrhagic pachymeningitis. A theory of a toxic condition in the first case could be well supported by the clinical history, but not so well in the case of internal hemorrhagic pachymeningitis, although even in this it could not be absolutely rejected. The alteration of the nerve-cell bodies throughout the central nervous system was extraordinary, although the secondary degeneration had not occurred. [T.M.T.]

3.—In a case of **muscular dystrophy** Chaddock notes that the beginning of the trouble was in the face, and it subsequently attacked the arms, and later the lower extremities became involved, and finally the hands. With atrophy far advanced and quite generalized, the wasting at the roots of the extremities predominates decidedly over that at the distal extremities of the members. The characteristic prominence of the middle third of the wasted deltoids is also worthy of note. Absence of all fibrillary contractions as well as the absence of all sensory and central disturbances are points which render a diagnosis of myopathic atrophy certain. [T.M.T.]

6. Cholesteatoma of the Temporal Bone and Its Treatment. H. J. WARING.

1.—Barwell has seen no cases of scoliosis in which, either while sitting, standing, or both, the pelvis was normally and properly placed. The **pelvic malpostures** with which we have to do are 3 in number: obliquity, amesiality, and version. Pelvic obliquity means that one side of the pelvis lies on a higher level than the other. It is, unlike the other two, not dependent on a trick or habit, but on a difference in length of the lower limbs. For the diagnosis of this condition the patient, having the garments let down to a level with the hips, standing with feet together and knees straight, is so arranged that there is some straight horizontal line in the decoration or furniture of the room in front of him that may serve as the gauge of level. The surgeon, behind the patient, places the index finger of each hand on the crest of one ilium at the side outline, and gets his eye at such a level that one of his fingers corresponds with the horizontal; unless the other finger also corresponds with the horizontal line the pelvis is oblique. Amesiality of the pelvis is a term indicating that the patient in standing erect habitually places the pelvis to one side of what should be the central mesial line of his figure. In order to diagnose this condition the patient should stand in drill posture, unless that position produces a swaying of the figure. In such a condition he may be allowed to stand with the feet slightly separated but at exactly equal distances from a carpet pin or other mark on the floor. Placing himself absolutely square behind, the surgeon so holds a plummet that it or its cord cuts the mark on the floor. If when traced upwards by the eye the cord does not fall over the intergluteal fissure, the pelvis is (probably) amesial. In order to carry out this method, the patient's back and hips must be bare and the feet must also be easily visible. The camera affords a much more certain diagnostic method, since the image can be accurately triangulated and measured. Version of the pelvis is a fault of posture that is very frequently met with. It is to be determined by measuring the distance from the rima narium to the pelvic side outline. Let a piece of white tape be pinned to the floor, and the patient arranged with the garments dropped a little below the level of the trochanters so that the heels touch its edge. The surgeon then holds some straight rod or sufficiently narrow strip of wood horizontally, and places its edge in equal contact against the patient's glutei muscles, then, stooping his head so that with the right eye he can look along the spine from between the scapulae downward, he notes whether his rod lies parallel to the tape, or cuts it at an angle somewhere between the heels. If one end of the rod lies behind and the other in front of the white line, the pelvis is verted toward the side on which the rod is posterior. The condition may be diagnosed while the patient is sitting. Of these three faulty postures obliquity very often occurs alone, the other two are less frequent; while occasionally all

three coincide in the same person. In the last case rapid and severe deformity is always produced. Pelvic malpostures do not originate in erect but in sedentary postures. A habit thus inaugurated in sitting very easily extends into the standing posture, and, although such juveniles as delight in athletic amusements may obviate the evil effects, yet many even of these suffer, while the more physically inert are certain to do so. A child detected by the means described sitting or standing askew should be intelligently corrected. Later curvature may be thus forestalled or, if incipient curvature is present, it may be redressed. [J.M.S.]

3.—In the majority of instances **intraperitoneal rupture of simple ovarian cysts** is apparently unassociated with discomfort. It is probable, therefore, that this condition is common in small cysts that have not given rise to any symptoms. The absence of symptoms is doubtless due to the innocuous contents of the cyst and to its slow escape, a sudden gush being prevented by the intraabdominal pressure. In a large proportion of recorded cases severe and dangerous symptoms supervened after rupture. In these instances the contents of the cyst must have been intensely irritating, and in many cases probably septic, while in a certain proportion death was produced by hemorrhage. The causes of rupture are numerous and include violence and morbid processes in the cyst wall due to thrombus and intracystic hemorrhage. Nutritive disturbances in the cyst wall, the result of tension of the pedicle, is a further frequent cause. Perhaps the commonest variety of cyst to rupture spontaneously is that with gelatinous contents. The gelatinous contents are, as a rule, more irritative and at the same time are but slowly absorbable by the peritoneum and may continue to distend the abdomen. It is, therefore, possible that this accounts for the greater frequency with which such cysts are found ruptured, because when the contents of a cyst are more fluid and more readily absorbed, operation is seldom undertaken after collapse of the cyst and the disappearance of the abdominal swelling. In a certain proportion of cysts with innocuous contents, in which, after rupture, no abdominal symptoms supervene, ready absorption of the extravasated contents occurs and permanent obliteration of the cyst follows. This occurs more frequently in unilocular cysts of the broad ligament, the fluid of which is practically normal saline solution and is absorbed rapidly, giving rise to temporary polyuria. In another series of cases there is a ready absorption of the escaped fluid, without peritoneal irritation, but the tumor reappears from redistention of the cyst or growth of secondary cysts. When, however, the contents of the cyst, though absorbable, tend to cause a subacute type of irritation of the peritoneum, we have inflammatory adhesions formed between the cyst wall and surrounding structures, which, on redistention of the cyst, may form an almost insuperable barrier to subsequent removal. In a fourth group of cases, practically lacerated cysts with gelatinous contents, no absorption takes place. At the same time, from mucoid degeneration of the cyst wall, the seat of rupture remains patent, and active secretion continues, which results in a steady increase of abdominal distention from free intraperitoneal fluid. According to Haultain, ruptured cysts should in all cases be removed as soon as possible. Having been certain of the presence of an ovarian tumor, its sudden or gradual disappearance should be an incentive to operation. The treatment of perforated cyst associated with acute symptoms must be operative. From our inability to diagnose the papillomatous variety without visual examination, and appreciating their tendency to secondary peritoneal infection, an additional incentive is added to the immediate removal of all ovarian cystic growths. Notes of 6 cases of ruptured ovarian cysts are given. [J.M.S.]

4.—Will be treated editorially.

5.—Littlejohn concludes that the hydrostatic test applied to the lungs is not an absolute means of determining that respiration has taken place, since in those exceptional cases of persistent atelectasis it may afford negative results, and yet the child may have respired for a considerable time. [J.M.S.]

6.—Waring reports one case of primary and one case of secondary **cholesteatoma of the temporal bone**. [J.M.S.]

9. Difficulty in Delivery as a Result of a Double Monstrosity. PALMEDO.

1.—Köster reports the case of a woman, 49 years of age, who had probably had luetic infection, and first manifested disease by lancinated pains in the legs, with numbness of the feet, some uncertainty in gait, etc. Ten years after the first symptoms she had at the menstrual periods crises in which she suffered from intense voluptuous sensations in the region of the clitoris, followed occasionally by a slight mucous discharge. These attacks were always followed by severe pains in the pelvic region, lasting for 24 hours, and afterwards by pains in the legs. The case has been steadily but very slowly progressing, and these symptoms have persisted for 10 years. The frequency with which the attacks occur varies considerably, sometimes every day or two; at others, only at intervals of a month. There were also crises in the larynx associated with pain and severe dyspnea. Treatment with bromides and baths produced considerable improvement. There were also severe pains in the left heel, which gave the patient much discomfort, and were resistant to all forms of treatment. These **clitoridian crises** are either very rare or have escaped observation. Two forms only have been described. One by Pitres, in which they are quite typical; another by Morselli, in which they are replaced by intense pains in the genitalia. The present case appears to combine both types. [J.S.]

2.—Meyer reports the case of a man 59 years of age, who sprained his right ankle. This troubled him for several days, although the pain was not severe. Fourteen days later a physician observed a distinct weakness in the right leg that gradually progressed until there was distinct paralysis. Later the left leg was involved; there were paresthesia, the reflexes were diminished or absent, but there was no disturbance of the bladder or rectum. It was observed that the muscles became weak and atrophic; there were no fibrillary twitchings, and there were distinct reactions of degeneration. There was no tenderness over the muscles or the nerves, and a diagnosis of **anterior poliomyelitis** was made on account of the regular progressive course of the disease, the fact that both legs were not affected simultaneously, the loss of the skin and tendon reflexes, the alteration in the electrical reactions, and the absence of objective disturbances or sensation. Slight paresthesia are not uncommon in anterior poliomyelitis. A diagnosis of ascending neuritis does not seem justified on account of the very slight pains in the beginning of the attack. [J.S.]

3.—Conradi has performed a number of experiments in order to determine what effect the **temperatures** used ordinarily in sterilization have upon the **chemistry of milk**. He found that the addition of calcium chloride favors coagulation considerably at a temperature of 55° until a considerable quantity is added, 1 part in 4 of a 10% solution, when it prevents coagulation completely. This action of calcium chloride is antagonized by the addition of sodium bicarbonate. Under these circumstances the temperature at which coagulation occurs can be considerably elevated, and after enough of the alkali has been added it will not coagulate, even at a temperature of boiling. In general it may be said that from 0.2 to 0.6% of calcium chlorid in cow's milk causes coagulation between 45° and 65°. If, however, the milk has first been heated above 80°, the temperature at which coagulation occurs is reduced from 8° to 12°, indicating an alteration in the casein. The period required for coagu-

lation may vary considerably. With ordinary rennet it was found for normal milk to occupy from 5 to 7 minutes. If, however, the milk had been heated to 80° the period was greatly prolonged, and if it had been boiled, it sometimes required many hours before coagulation occurred, if at all. Conradi therefore recommends that in sterilization temperatures of less than 75° be employed. [J.S.]

5.—Koppen reports some interesting cases bearing upon the **diagnosis of gonorrhea**. One of these, a boy of 17 who had been exposed, was found to have, not gonorrhea, but tuberculosis of the testicles. Another, a man of 60, with tuberculosis, was found to be suffering from acute urethritis. He reports several other cases in which infectious processes had remained latent for a number of years, and then, as a result of some irritation, had suddenly developed. He calls attention to the great importance of careful microscopical examination, and believes that by it we are frequently in a position to make a diagnosis even although a urethroscope is not available. No case is to be recorded as cured until all discharge ceases. [J.S.]

6.—Scholtz believes that the present agitation concerning venereal infection is having considerable success among the German students, particularly in regard to leading them to seek treatment promptly. [J.S.]

7.—Loeb has performed some experiments in order to determine the efficacy of **formalin disinfection**, particularly for catheters and similar instruments. For this purpose he used cultures in gelatine in order to render the access of the disinfecting agent to the germs as difficult as possible. He found that mercuric cyanide solution acted in 6 hours upon the spores of anthrax at a temperature of over 70°, but failed to act in 7 days at normal temperature. He found that formalin vapor destroyed these spores in 6 hours, although this did not occur if the tubes were plugged with cotton. Bouillon cultures were destroyed in 2 hours. He believes that it is important to use some method of mechanical cleansing before the application of the disinfectant. Catheters he sterilized by allowing a solution of corrosive sublimate, 1 to 1,000, to run through them for about 24 hours. This invariably destroyed all spores. [J.S.]

8.—Sternberg reports a case of **ischiopagus**. Delivery was accomplished by extracting first one child and then doing version upon the other. Both portions of the monster died at birth, although one made a few efforts to breathe after delivery. The monster consisted of two heads and necks, four well-proportioned arms, two well-developed legs, and a single, considerably shrunken limb. There were two spinal columns, and two thoraces, which, however, were included in the common skin covering, but only one pelvis. [J.S.]

9.—Palmedo reports another case of **double monstrosity**, which was delivered with great difficulty, one child living about an hour, the other dying at birth. The children were apparently united along the ventral surfaces. [J.S.]

1.—Funke reports 19 cases in which he performed **total extirpation of the uterus on account of malignant tumor**. Three died within a few days of the operation,

and the others recovered, but it is still too early to speak positively of the absence of recurrence. He discusses particularly the indications that are given by enlargement of the glands. In 16 cases out of 40, those upon which the operations have been performed most recently, this enlargement was carefully sought for and found in 8. Of these 8, two showed such extensive metastasis that a radical operation was not possible. In 2 others the glands could not be removed on account of extensive adhesions. In another 2, both young women with carcinoma of the cervix, in spite of extensive removal of the glands, recurrence appeared within 5 months, showing that the operations had not been radical enough. In one of these the recurrence appeared on the side from which the glands had been removed. Of the remaining 2 cases, one has shown no recurrence since 1896, and 1 had only recently undergone operation. Funke prefers the combined vaginal and abdominal routes. He believes that the operation should not last longer than any other severe laparotomy, that it should be very thorough and involve the removal of the chain of glands along the iliac arteries and the ureters, and the complete removal of the parametrium and the lymphatics connected with it. The prognosis of carcinoma in young women, that is to say, those about 30 years of age, is very doubtful, on account of the extremely rapid growth of the tumor, and the fact that metastases may occur before adhesions may have formed. In older women the progress is more gradual. It is very difficult therefore, to say which cases are adapted to a radical operation, and which to a palliative one. The higher mortality of Freund's operation, which was the one used by Funke, is apparently due in part to defective technic, for in his own experience the percentage of deaths has steadily decreased. As for the possibility of permanent cure the following figures show that it is not inconsiderable. In 11 cases operated upon before 1896, 2 died immediately after the operation; 4 of recurrence, and 5 are still living and apparently well. Of these cases 2 were sarcomas, 1 carcinoma of the cervix, 1 of the body of the uterus, and 1 of the entire organ. [J.S.]

2.—Wilms reports the following cases of **tetanus in which the antitoxin was employed**. A man of 26 received a severe wound in the knee-joint requiring amputation six days later. Eight days after the injury there were symptoms of tetanus, and 250 units of antitoxin were injected on that day, and on each of the following three days. The patient died on the fourth day of the disease without any improvement. A man of 39 received a severe crush of the skin of the left leg. On the eighth day symptoms of tetanus appeared, and on the following day an injection of 250 units was made. The patient died the same day. The third case, a boy of 18, was injured upon the right foot. On the seventh day the symptoms appeared and 20 hours later 125 units of antitoxin were injected, and a similar amount in three hours. The next day 250 units more were injected and on the third day death occurred. The fourth patient, a man of 22, received an injury to his hand; on the ninth day the symptoms appeared and on the same day 1,000,000 units were injected, and within the first 30 hours altogether 4,000,000 units. No improvement of any kind was observed, and the patient died. In all these cases the conditions which Behring requires to be fulfilled were carefully observed, that is that the serum treatment shall be commenced in 30 hours after the first symptoms have appeared, and that not less than 100 units shall be injected. Nevertheless all the patients died. Wilms reports also two cases of chronic tetanus in both of which the serum was employed, and both of which recovered. In both cases, however, the serum was not employed until the third day. [J.S.]

3.—Berndt, in the first portion of a valuable paper on **appendicitis**, or, as he prefers to call it, **epityphlitis**, speaking of the etiology of the disease, discards entirely the idea of stercoral typhlitis, that is to say appendicitis caused by an accumulation of feces in the cecum; however, he adheres to the view that the majority of cases are caused by some fecal concrement or foreign body in the lumen of the appendix itself, which may cause perforation by pressure, or by setting up an inflammation that distends the appendix and finally ruptures it. In a series of operations he obtained a number of specimens which show practically all stages of the disease, and curiously enough, vary in length from 4 to 20 cm. He accepts the conclusions of Sonnenberg, who recognized the following types: First, acute catarrhal epi-

typhlitis; second, chronic catarrhal epityphlitis; third, perforative ulcerated epityphlitis (*a.* with circumscribed peritonitis, *b.* with diffuse peritonitis). He gives the symptoms of the three types as follows: Acute catarrhal epityphlitis not infrequently accompanies acute gastroenteritis; it is characterized by moderate pains in the iliac region, tenderness over McBurney's point, and in some cases a palpable appendix which may be felt as a cord and is recognized by the patient as the seat of pain; chronic epityphlitis usually occurs in patients who have suffered from digestive disturbances for years. They have loss of appetite, occasionally vomiting, diffuse abdominal pains, and constipation or a tendency to diarrhea. The disease not infrequently occurs in young girls, and may be confused with chlorosis. Upon physical examination the appendix may sometimes be felt as a painful cord, and there is nearly always tenderness over McBurney's point. To this class belongs a group of cases characterized by frequently repeated attacks of pain usually localized in the right iliac region, and accompanied by vomiting and fever, and either constipation or diarrhea. These attacks last usually only a few days. Then finally the patient has a very severe attack characterized by high fever, weak and rapid pulse, and then the formation of an exudate in the region of the appendix. If the symptoms persist, the differential diagnosis from perforative epityphlitis is difficult. Ordinarily, however, the symptoms rapidly diminish, the exudate disappears, and in 8 days there are no further traces of disease. If an operation is performed the appendix is usually found slightly adherent, with thickened and rigid walls. Perforative epityphlitis usually occurs in patients who have had numerous typical attacks, or at least occasional pains in the abdomen. In a few cases no previous symptoms have occurred; these patients are usually robust. The symptoms are a sudden pain in the abdomen, vomiting and high fever often associated with chills, superficial respiration, and small rapid pulse, with an expression of extreme anxiety upon the face, which is often covered with sweat, and a retracted and rigid abdomen. In the course of a few hours or days the pain becomes localized in the right iliac region; the abdomen is slightly distended, there is resistance in the region of the appendix, distinct dullness on percussion and exquisite tenderness. From this point different cases pursue different courses. In some, symptoms of septicemia develop, and the patient dies within 24 hours; in others, they become mild, and in spite of perforation the patients gradually improve. Berndt believes that this is not due to previous walling off of the appendix by adhesions, but rather to the different degrees of virulence of the microorganisms, for in his opinion the contents of the appendix are always expelled into the free peritoneal cavity. In a few cases the pain is felt on the left and not on the right side. In all cases it is extremely important to watch the pulse and the temperature in order to control as far as possible the condition of the patient. In regard to treatment his opinions are interesting. The first form does not require operative interference. The second form, the chronic catarrhal, can be cured only by removal of the appendix. The operation is best performed during an interval. The third form may occasionally heal spontaneously, but no physician should depend upon this. Nevertheless, as the great majority of the cases of perforative epityphlitis pass into a latent stage if treated expectantly, it is obvious that every case should not be subjected to an operation as soon as the diagnosis is made. The choice, of course, depends entirely upon the experience of the surgeon. If the symptoms are grave from the first, an immediate operation is demanded. If, on the other hand, they are mild and steadily improve, expectant treatment is probably the best. [J.S.]

4.—Kromayer and Grüneberg believe that in *eczema* the following indications should be met. Rest of the skin, the removal of the chronic changes in the tissue, and the cauterization of the inflammatory areas. The latter procedure is one that most frequently, if improperly used, causes disaster. *Lenigallol* is the best drug for the treatment of *eczema* that has hitherto been introduced. It is the triacetate of pyrogallol-acid, and occurs in the form of a white crystalline powder, insoluble in water. Brought into contact with skin in a seat of chronic inflammation, it gradually yields free pyrogallol acid. On healthy skin it is entirely nonirritating. The authors have used it in about 600 cases with very excel-

lent results. They employ either 20 parts in 8 parts of zinc paste, or 10 parts mixed with tar and zinc paste, or mixed with Wilkinson's ointment. The zinc paste mixture is used in the milder cases and ordinarily all the inflammatory parts are colored black at the end of the first day. In the deeper cases one of the other preparations is used. In a few cases the results are unsatisfactory because the caustic action is too slight. [J.S.]

5.—Rumpel criticizes the statements of Waldvogel who discovered a remarkable reduction in the **freezing point of blood obtained from typhoid fever cases**. He has repeated these experiments and found that by various technical procedures, or by the dilution of normal blood-serum, an artificial reduction could be obtained. In 11 cases of typhoid fever with varying temperatures he has carefully estimated the freezing point of the blood, and found that it was exactly normal. [J.S.]

6.—Witthauer reports a remarkable case, a woman 24 years of age, who was attacked with pains in the side, cough, and fever. Examination showed an area of dullness on the left side in the region of the lower lobe, in which the breath sounds were weak. Exploratory puncture gave a clear fluid. There was some hectic fever. A second aspiration gave again a small quantity of fluid. For a period of 5 months the patient had a regularly relapsing fever, the remissions lasting 3, rarely 4 days. Then on the fifth day the temperature rose to 39° or 40°, fell the following day to 38°, and the next day became normal. Careful examination of the blood for malarial parasites was negative. No antiseptic measures nor specific treatment had any effect whatever. In the last month the patient showed slight cyanosis of the face, pulsation of the vessels in the neck, and then gradually increasing symptoms of bronchial stenosis that led to death. At the autopsy a large **tumor** was found in the **posterior mediastinum** about the size of two fists. It had invaded the posterior walls of both auricles. It also compressed both bronchi and the left branch of the pulmonary artery and had invaded a considerable portion of the right lung. Microscopically, it proved to be a round-celled sarcoma. The interesting features were the regularly recurring fever and the invasion of the heart. [J.S.]

7.—Model, after a careful analysis of the facts regarding the existence of the *menabea veneata baillon*, reaches the conclusion that this plant does exist, belongs to the *ordalia*, and that it is exceedingly important that fresh specimens should be obtained from Madagascar and carefully studied in relation to their toxicity. [J.S.]

8.—Reismann suggests a simple **apparatus for supporting the uterus**, consisting of a rubber tube stuffed with cotton, and supported at its lower end by 2 other tubes that fasten into the belt. For more accurate description we refer the reader to the original article. [J.S.]

9.—Wilde clears **agar** with the white of egg; then, after prolonged boiling, is able to **filter** it quite rapidly. He believes this method is quite as good as that of Paul. [J.S.]

9. Remarks upon the Article of Dr. Frank: "The Disinfectant Action of Alcohol, Especially of Alcohol Steam." V. BRUNN.

1.—Kunik discusses the technical points involved in the **transplantation of tendons for the correction of deformities** of the feet and hands. The various procedures may be roughly grouped as follows: First, the transplantation of the central portion of a healthy muscle into

the tendon of a paralyzed muscle; second, the division of the tendon of a paralyzed muscle and the implantation of its peripheral portion in the healthy muscle, sometimes called "passive transplantation"; third, splitting of the tendon of a healthy muscle and the implantation of one half into the tendon of a paralyzed muscle, sometimes called "active transplantation"; fourth, the implantation of a healthy tendon in the periosteum. In addition to the transplantation of the tendons it is often necessary to employ other operative measures, such as correction of the position, etc., before the transplantation is undertaken. In those cases in which contraction of the muscles antagonistic to the paralyzed muscles has occurred, it is necessary to elongate the tendons by making a series of step-like incisions. Another important procedure is the resection of the tendons of healthy muscles that as a result of vicious position of the extremity have become abnormally elongated. Of course, in many cases it requires a combination of all methods in order to secure the desired result. In addition to infantile spinal paralysis deformities due to injury, or those that are congenital, may be operated upon by these measures. The operation should be undertaken only when cure by any other measure is manifestly hopeless, and as long as traces of spontaneous improvement appear it should be delayed. After the operation the extremity is placed in the position of over-correction and fixed in a plaster cast. [J.S.]

2.—Steudel calls attention to the fact that certain of the lower forms of life, particularly bacteria, are capable of living at temperatures nearly as high as those that coagulate albumin, that is to say, they not only maintain life, but actually multiply actively at from 60° to 70° C. These microorganisms under anaerobic conditions, particularly if associated with other forms, can multiply at other temperatures. It is interesting to note that certain other lower forms of life can resist high temperatures if sufficient water has been abstracted from them. This is particularly true of the rhizopods. Certain rhizopods are capable, as a result of careful cultivation, of supporting a temperature of 70° C.

3.—Fleischmann reports a case of inversion of the uterus occurring in a primipara. After delivery the uterus remained relaxed, and during an effort to expel the placenta by Credé's method, the uterus suddenly became completely inverted, and the patient immediately went into collapse. Upon an attempt to replace it, it was found that the cervix opposed an obstacle, but this was overcome by gentle force. After replacement, the uterus remained relaxed until a warm injection was given, when it immediately contracted, and the subsequent course was normal. He also reports another case that occurred in the service of Dr. Becker, in a multipara, which, however, was easily replaced. In a few remarks upon this condition Fleischmann mentions the collapse that is so common, and is peculiar in that it disappears almost immediately after reposition. The chief obstacle to this is the cervix. This can best be overcome by inserting the fingers, then gradually distending them, and at the same time pressing upon the fundus with the hollow of the hand. The placenta probably always should be removed before reposition is attempted, partly because if this is not done inversion is apt to recur and, moreover, reposition is always more difficult. [J.S.]

4.—Schaller states that in those cases in which the patient has a small myoma of the uterus that does not produce symptoms, he does not advise an operation, nor does he even tell the patients that they have a tumor. Large myomata produce merely mechanical disturbances; small, intramural myomata frequently cause an obstinate dysmenorrhea. In a few cases the myomata become malignant, and then endanger the life of the patient. In all cases in which they undergo suppuration, gangrene, or sarcomatous changes, they should be removed. In case the patient should become pregnant, they usually develop very rapidly. Schaller believes that a conservative treatment is often of great advantage. Thus, the patients can be considerably improved by rest in bed during menstruation, moderate purgation, ice-bag upon the abdomen, and a general improvement in the nutrition. Certain hemostyptics are of value, especially hydrastis, and occasionally ergotin. Locally, hot douches to the vagina may be employed, or certain escharotics to the mucous membranes, such as tincture of iodine, carbolic acid, etc. Electricity does not appear to be of value. Ovariectomy is some-

times of value, particularly in patients suffering extreme cachexia, in whom an operation might be dangerous. In submucous myomata, a vaginal enucleation may be employed, although in these cases recurrence may appear. In the more severe forms, the combined vaginal and abdominal operation is probably the best. [J.S.]

5.—Guttenberg reports 5 cases occurring in women, in which the symptoms were pain in the lower portion of the abdomen, and in whom, upon careful examination, small nodules were found along the cord of the sacral plexus, that, according to Rindfleisch, who examined a similar case, consist of an accumulation of small cells with round or oval nuclei; that is, a form of neuritis nodosa. In all these cases cure was obtained by careful attention to the general condition, and systematic massage of the nerves, with hyperflexion of the thighs upon the abdomen. Cure usually required several weeks. [J.S.]

6.—Sternfeld highly recommends china acid, obtained from various fruits, in the treatment of uric-acid diathesis. This is converted into benzoic acid, and finally into hippuric acid in the body, and when combined with the uric acid promotes the elimination of the latter. The great objection to it at present is its high price. [J.S.]

7.—Berndt, in continuation of his article upon epityphlitis, discusses the methods of operation. The object should always be to reach the site of the primary abscess. The operation is always serious, and is not to be undertaken unless absolutely indicated. A double operation is entirely irrational. When a typical attack has occurred, should the patient recover, operation should be performed 3 or 4 days after the disappearance of the fever. In cases with a mild course, there may sometimes persist a remittent fever, rising in the evening. This usually indicates the existence of a large encapsulated abscess. When this is opened the appendix should be removed if easily found, but it is undesirable to take great pains to search for it. Berndt prefers an oblique incision parallel to Poupart's ligament, and passing through McBurney's point. This is continued through the muscles and fascia until the site of the operation is reached. During an interval the operation is usually more difficult because the adhesions are denser. If the operation is done during an attack, it is usually desirable to tampon the entire wound. The results in 40 cases were as follows: Operation during an interval—15 cases, all cured; made after an acute attack—7 cases, all cured; opening of a large encapsulated abscess after a long febrile period—5 cases, all cured operated upon during an attack (1) without perforation of the appendix—2 cases, both cured; (2) with perforation or gangrene of the appendix—11 cases, 5 cured and 6 died. Three of these were operated on in a state of collapse. Twenty-four of these patients were subsequently observed, 3 had hernia in the wound; all were operated upon during an attack. The others were normal with the exception of 1 who had a very small tumor upon coughing. Two patients had intestinal fistulas; one of these closed spontaneously, the other was not closed by two operations. The histories of the cases are given in detail. [J.S.]

8.—Schmidt-Monnard has observed several cases of diphtheria in which he was obliged to use old serum, and his impression has been that it acted much less efficiently than fresh serum. [J.S.]

9.—Von Brun believes that in disinfection with alcohol the vapor is the effective element. He is delighted that his results have been confirmed by Frank. [J.S.]

1. Total Extirpation of the Vagina Through the Abdomen. ERNST WERTHEIM.
2. Remarks upon Total Extirpation for Myoma Through an Abdominal Incision. H. A. v. GUERARD.
3. Contribution to the Etiology of Sactosalpinx with Torsion of the Pedicle. J. HARFÖTH.
4. Critical Reports on the Speculum of Professor Dr. Draghiescu. Z. SINTENIS.

1.—Wertheim reports 2 cases of total extirpation of the vagina through the abdominal incision for cancer of that organ secondary to carcinoma of the cervix. His first

patient was a woman, 56 years of age, who presented a cancerous ulcer the size of a walnut upon the anterior vaginal wall, which was accompanied by a slight hemorrhagic discharge. He performed the radical operation through a sagittal median incision, extirpating not only the uterus, but the upper portion of the vagina and a portion of the posterior vaginal wall. No prophylactic catheterization of the ureters was resorted to. Considerable venous hemorrhage from the paravaginal cellular tissue followed the extirpation, but this was easily controlled by ligature. The lymph-glands in the vicinity were also extirpated, the peritoneal edges were closely coapted, and subperitoneal drainage into the vagina was established by iodoform gauze. The patient made an excellent recovery. The second case was a woman, 51 years of age, upon whose portio vaginæ existed a white carcinomatous growth the size of an apple. The posterior vaginal wall also presented multiple small and large capillary outgrowths. A similar operation as in the foregoing case was performed. The carcinoma had descended pretty close to the bladder-wall and had surrounded the ureter; as a result a left-sided uretero-vaginal fistula followed, otherwise the operation resulted well. Three months later a nephrectomy was performed for the relief of the fistula. [W.A.N.D.]

2.—Guérard considers the question of **extirpation of myomata through the abdominal incision versus total extirpation of the myomatous uterus**, which was first discussed by Hofmeier. He is inclined to prefer the total extirpation of the uterus through the abdomen to the mere amputation of that organ at the cervical junction. The operation consists, after opening the abdomen, in enucleating the tumor and then opening into the vaginal fornices anteriorly and posteriorly and securing the vaginal wall to the peritoneal edges. The hemorrhage is but slight, and the operation takes from but 30 to 36 minutes, requiring not more than three ligatures in some cases. He has removed by this method tumors weighing 11 pounds or more and varying in size from that of a child's head to a man's head. [W.A.N.D.]

3.—Harpöth records a case of **sactosalpinx with torsion of the pedicle** in addition to the 22 cases of this condition recorded in 1899 by Praeger in the *Archives für Gynäkologie*, Bd. lviii, Hft. 3. His case was a young woman, 26 years of age, who suffered from severe pains in the right side of the abdomen, the pains localizing themselves in the right iliac fossa. In the intervals between the pains the patient felt quite well. Menstruation had always been regular, lasting four days and was unattended with pain. The patient had been suffering for some time from metrorrhagia. Abdominal palpation revealed a tumor extending above Poupert's ligament, while vaginal examination showed the uterus lying well up in the pelvis and small in size. The tumor could be felt lying on the right side and extending posteriorly into Douglas's culdesac. It fluctuated on percussion, was sensitive to the touch and was about the size of a small child's head. It had a broad pedicle. The ovaries could not be detected, and there was no ascites. Operation revealed a tubal tumor which was slightly adherent and which had twisted upon itself, producing torsion of the pedicle. The tube was ligated and extirpated. Harpöth remarks that sactosalpinx usually occurs in a tube which is quite free or but slightly adherent to the surrounding tissues; this was the case in his own instance of the complication. [W.A.N.D.]

January 5, 1901.

1. Operation for Hernia of the Umbilical Cord with Resection of the Prolapsed Lobes of the Liver. OTTO KÜSTNER.
2. Additional Remarks on the Use of Protargol by Credé's Eye Instillation-Method. FRITZ ENGLEMANN.
3. Another Case of Hypertrophy of the Female Mammary Glands. A. GRASMÜCK.

1.—Küstner reports an interesting case of a male child admitted to the Polyclinic in Breslau presenting a large-sized **umbilical hernia**, as large as an apple, associated with prolapse of the liver. A portion of the latter organ projected through the opening in the abdominal wall and into the hernial sac. The umbilical cord was inserted into the lower half of the sac. It was 34 cm. in length and showed 3 vessels, 2 arteries, and 1 vein. The operation

which was performed for the relief of this condition consisted in drawing the sac out, cutting it off with scissors, and suturing the edge of the sac to the thin peritoneal covering of the abdominal wall. It was found necessary to remove a portion of the prolapsed liver. The vermiform appendix, together with a portion of the ascending colon, lay in view under the thinned-out peritoneal covering. The adhesions to the liver were separated and the liver as far as possible restored to its normal position. Although not narcotized, the child during the operation did not suffer any pain, except when extra pressure was exerted upon the prolapsed organ. A normal convalescence followed. [W.A.N.D.]

2.—Englemann gives a brief critical review of Zweifel's article, published in No. 51 of this journal, 1900, on the **prophylaxis of ophthalmia neonatorum** by Credé's method. He especially speaks of the results obtained by the use of silver salt, protargol, which he claims are very bad in a number of cases, silver catarrh being produced in over 48 children. [W.A.N.D.]

3.—In the *Centralbl. f. Gynäk.*, No. 35, Donati reported an interesting case of **mammary hypertrophy** from Ehrendorfer's clinic at Innsbruck. Grasmück records an additional case, giving the following history: The patient, a peasant woman, 18 years of age, presented herself at their clinic in the last month of her first pregnancy. As a girl she had always been healthy; menstruation began when she was 16, and was regular. The mammary glands were of normal size. The patient married 10 months before she presented herself for treatment. In the second month of her pregnancy she had, for the first time, noticed an unusual size of the breasts, which became so large and heavy as to fall down to and rest upon the abdominal enlargement. They were so large as to require constant support from a mammary binder. The subcutaneous veins were distended, but not varicose. The right breast was considerably smaller than the left, although the tissues were firmer. Grasmück regards this case as one of true mammary hypertrophy. [W.A.N.D.]

Neurologisches Centralblatt.

February 1, 1901. [No. 8.]

1. A New Method of Silver Impregnation for Staining the Axis Cylinders. (Preliminary Communication.) FAJERSZTAJN.
2. The Value of the Measurement of Blood Pressure in the Diagnosis of Traumatic Neurasthenias and Hysterias. STRAUSS.
3. A Case of Myasthenia Pseudoparalytica Gravis. MENDEL.

1.—The principle of this **new silver stain** is as follows: Ammonia added to a solution of silver nitrate causes a precipitate that is soluble in excess of ammonia. If to the latter an aldehyd is added, the liquid becomes cloudy, and after some time the sides of the test tube are covered with a mirror, or if the reaction occurs very energetically a black precipitate is thrown down. The tissue is hardened in a 5 to 10% solution of formalin for several days to several months. It is not necessary that the tissue should be very fresh. The tissues are best cut in the freezing microtone, and then thoroughly washed in water. A 2% solution of nitrate of silver is prepared, and to this ammonia is added drop by drop until the preliminary cloudiness has completely disappeared. Then some of the 2% solution of silver is added to this until a yellow precipitate appears, the solution is then filtered through an analytic filter. No free ammonia now exists in it, and it stains very effectively. It is usually advisable to add a small quantity of baryta water to this. Various mixtures are prepared with a mother solution containing 1 to 2 drops of ammonia, of sodium hydrate, or of baryta water, and several sections placed in them. Impregnation usually occurs in from 5 to 20 minutes. The sections are then placed immediately in a 5% solution of formalin, and allowed to remain for an instant, and then examined in a drop of formalin under a microscope. The axis cylinders are stained an intense brown or black, the nerve-cells are either invisible or stained a faint yellowish brown. Sometimes the nuclei, and sometimes the red blood-cells are also stained, and occasionally the glia cells and glia fibers are slightly colored. If there is too much alkali present the sections are stained a diffuse brown, and if there is too much ammonia

they do not stain at all. If this is the case the process can be repeated several times. If necessary to differentiate the sections, and this may be the case in tissue hardened in Müller's fluid, it can be done by placing them in 10 to 15 ccm. of 95% alcohol solution, to which 1 to 3 drops of a 0.3% solution of chlorid of gold has been added. They are allowed to remain in this in the dark for about 24 hours. Platinum chlorid may also be used. The sections are then mounted in Canada balsam. The author describes the results he obtained in sections from various parts of the body. Certain modifications are required if the tissue has been hardened in Müller's fluid. He expresses the hope that the method may in time be so greatly improved as to add a valuable microchemical test to our laboratory methods. [J.S.]

2.—Strauss calls attention to the fact that the **elevation of blood-pressure** as a result of peripheral stimulation, may be of considerable value in the **diagnosis of traumatic neurosis**. He used chiefly the method of Gerhardt, and performed the experiments between 10 and 12 in the morning, upon the left index finger which was held at the level of the heart. In normal human beings the average pressure was between 90 and 100 mm. of mercury. In 9 cases of uncomplicated traumatic neurosis he found in 25 investigations that in 21 the pressure was between 100 and 120 mm., in 3 cases below 100 mm., and in one case over 130 mm. When the sensitive point of which these patients complained was pressed upon there was an increase in blood-pressure of from 15 to 40 mm. In normal human beings this increase in pressure is considerably less. [J.S.]

3.—A servant, 21 years of age, developed pain in the left leg, then difficulty in speaking, and swallowing. She was easily fatigued and often had cramps in the calves. When examined it was found that the pupillary contraction to light was very transient, and soon disappeared; all the muscles became readily fatigued, there was slight paresis of the right facial nerve. The pharyngeal reflex was absent, the speech was bulbar in type, and there was rapid fatigue of the extremities. The pulse was extremely irregular, and there was often dropping of one beat. Later a typical myasthenic reaction occurred, and the diagnosis of **myasthenia pseudoparalytica** was made. The only etiologic factor that could be discovered was a very pronounced tuberculous family history. [J.S.]

Journal des Praticiens.

February 23, 1901. [15me Année, No. 8.]

1. The Symptoms of Dyspepsia in Older Children. SEVESTRE.
2. The Pathogeny of Gallstones. G. LIROSSIER.
3. The Association of Dyspnea and Angina Pectoris. H. HUCHARD.

1.—The main symptom, **headache**, is almost **constant in children suffering from dyspepsia** during the period from 7 to 15 years. There is also present a tired feeling, with perhaps fever, palpitation, or nervous symptoms. The headache is generally frontal, and persists. While the headache is absent at night, insomnia or nightmares occur. Palpitation is common upon the slightest exertion, and arrhythmia, with an occasional functional murmur, is also observed. Vomiting may appear, with fever, off and on. The stomach and colon are both found dilated. The liver may be enlarged, and constipation is the rule. The tongue may be coated and the breath foul. These children eat quickly, and often drink too much liquid at meals. **Sevestre believes the headache to be due to an intoxication** from indigestion. Therefore, treatment should be directed toward preventing the formation of such toxins, and toward destroying them if already formed. Diet is to be insisted upon, and all food properly masticated. Meals must be regular; bowel movements also. Tincture of nux vomica should be given before meals. Finally daily bathing and exercise in the open air are necessary. [M.O.]

2.—It has been shown by experiment lately, that **gallstones may be due to microorganisms**. The two bacteria which are known to have caused them are the colon bacillus and the typhoid bacillus. The latter will cause the renewed production of gallstones in a person whose gallbladder was affected before taking typhoid fever. Thus, the condition of the part affected will often favor the inva-

sion of bacteria. To keep off such disastrous effects, in those predisposed to gallstones, by heredity, gout, etc., Linossier advises regular yearly visits to some alkaline springs, in order to maintain a good condition of general health. [M.O.]

3.—Huchard reports the case of a man of 63, who neither smoked, drank, nor had had syphilis. For 18 months he has suffered from dyspnea upon the slightest exertion, accompanied by a feeling of oppression. During the last 3 months this has increased so that he can only sleep with difficulty. There is a little albumin in the urine. During this time he has had a few attacks of true **angina pectoris**, first with exertion, later even at night. They are severe and of short duration. Besides, during the past few weeks, he has had **pseudostenocardia**, the pain persisting, localized to the second intercostal spaces on both sides, and to the right shoulder. Upon auscultation the diastolic shock of the aorta is heard, and some arrhythmia. The pseudostenocardia Huchard believes to be neuralgic or neuritic, secondary to the periaortitis evidently existing there. But true angina pectoris also exists, due to probable endoaortitis. The "toxi-alimentary" dyspnea depends upon the renal sclerosis, just as true angina depends upon aortic and coronary sclerosis. As treatment he advises exclusive milk diet and theobromin for two weeks. Then for one week every month, milk diet and sodium iodid. During the rest of the month, special diet, with the theobromin continued. Huchard considers this alimentary treatment most necessary in this complex case of **mixed angina pectoris with pseudostenocardia**. [M.O.]

March 2, 1901. [15me Année, No. 9.]

1. Typhoid Fever and Pleurisy. PAUL REMLINGER.
2. Seven Cases of Shoe-Polish Poisoning. LAURENT and GUILLEMIN.
3. Heteroplasty of the Orbit, with the Use of a Rabbit's Eye. F. LAGRANGE.
4. The Treatment of Syphilis During Pregnancy. GAUCHER AND BERNARD.

1.—**Pleurisy may occur with typhoid in four different ways**. First, the pleurisy may be but the first symptom of beginning typhoid, the diagnosis only being settled by the Widal reaction, after epistaxis or spots have appeared. This the French call "**pleurotyphus**." Then pleurisy may occur as a complication, late in typhoid, with a serous, hemorrhagic, or purulent effusion. While three-quarters of the cases recover, the development of pleurisy is always serious. Rarely a pleurisy in typhoid will be due, not to the bacillus of Eberth, but to some secondary infection. Rarer still is a pleurisy caused by the typhoid bacillus, in the terminal stage of acute phthisis, of which 2 cases are reported, no signs of typhoid fever being found at the autopsies. [M.O.]

2.—Six children in one family, all of whom had worn shoes fresh from the shoemaker, upon which the aniline polish had not yet dried, were attacked suddenly with symptoms of **poisoning**. Their ages ranged from 2 to 14 years, the youngest being the earliest affected. First, pallor of the face, a bluish discoloration of the skin, and a violet color of the lips and nails were noted; then dilatation of the pupils, headache, vertigo, absolute muscular weakness, transitory paralysis, followed by unconsciousness, slowing of the pulse, and arrhythmia, with cold extremities. Slight convulsive movements occurred in 2 cases, besides. In from 1 to 3 days all signs disappeared, including the faint trace of albumin found in the urine. Another case occurred later, in a child of 6. A thorough investigation revealed the fact that in each case the shoes worn had but just come from the shop, and the polish was not yet dry. Chemical examination of the polish used showed **aniline**. Experiments were made upon guineapigs, in which the polish produced precisely the same symptoms as in man. [M.O.]

3.—Lagrange reports 4 cases of operation for loss of vision following traumatism. Three have been quite successful. In each case the **eye was enucleated**, a thread left in the muscles. The hemorrhage was then stopped, either by irrigating with ice-water, hydrogen peroxide, or by a tampon left some time in the capsule of Tenon. Then a **rabbit's eye**, preferably of a young animal, is enucleated, and sutured in the patient's empty capsule. Then

the conjunctiva is sutured at four points and an ordinary occlusive dressing applied. At the end of a week, the conjunctival stitches are removed. [M.O.]

4.—Gaucher and Bernard say that **pregnancy occurring in syphilitics who are well treated is not as serious** as it is generally considered. If specific treatment be begun early enough, and given in large enough amounts, regularly, well children will be borne at term. Such children should be nursed by their mothers, and treated, to prevent later syphilitic manifestations. The treatment advised consists of injections of two centigrams of benzoate of mercury, daily, alternating with pills containing two centigrams of bichloride of mercury, the number of injections being continued over a period twice as long as that of the pills. The intensity of this treatment, if the woman should show albumin in the urine, should be subordinated to the renal function, which can be watched by determining the urinary toxicity, and the elimination of the mercury. [M.O.]

Gazette Hebdomadaire de Médecine et de Chirurgie.

February 10, 1901.

1. Dyspeptic Glycosuria and Diabetes. ROBIN.
2. The Role of the Renal Plexus in the Pathogenesis of the Edema of Bright's Disease, and of Some of the Symptoms of Nephritis. M. F. SÉMERIL.
3. Treatment of Infantile Tuberculosis by Thiocol. KAPLANSKY.

1.—At the meeting of the *Académie de Médecine* held February 5, 1901, Robin read a paper on **dyspeptic glycosuria and diabetes**. As a complication of dyspepsia, simple glycosuria is met with in 5% of the hypersthenic cases. It is irregular, always small, varying from 0.05 to 6 grams per liter. It only exists in the urine during the process of digestion and is wanting in the fasting urine. In half the cases it coincides with digestive albuminuria. The elementary nutrition is characterized in these patients by an exaggeration of the nutritive changes and of the dissimilation of nitrogen and by the excitation of the nervous system. There are no symptoms of diabetes. The patient has only an exaggerated appetite, a distended stomach, an hypertrophied liver, and gastric hyperchlorhydria. One finds also vertigo, phosphaturia, dermatoses, hyperidroses, ocular and auricular troubles. If, in a certain number of cases, gastric troubles are secondary to diabetes, the rule is for diabetes to be consecutive to dyspepsia. This distinction is important because dyspeptic diabetes may yield to treatment while primary diabetes ordinarily resists treatment. This diabetes, as has already been demonstrated, is not a disease characterized by a depression of nutrition, but, on the contrary, by an excitation of nutrition and an increase in the activity of the liver. In fact, all the medicines that excite nutrition aggravate diabetes; whilst those medicines that moderate nutrition ameliorate diabetes. For example, antipyrin diminishes glycosuria, pyramidon augments it. Glycosuria always indicates an hyperactivity of the hepatic function; it is in relation with gastric hypersthenia of the dyspeptic subjects in whom it is observed. The excitation of the liver, at first intermittent, may become permanent, and true diabetes of dyspeptic origin is then set up. Glycosuria of dyspeptic origin is cured by the treatment of the hypersthenic dyspepsia; the administration of powders of the alkaline earths after meals often suffice. In cases that are more severe, absolute milk-diet gives good results, whilst, on the other hand, it is well known that milk diet is unfavorable in cases of true diabetes. When dyspeptic diabetes is established the treatment is commenced by decreasing the quantity of sugar by diet. Then the dyspepsia should be treated. [J.M.S.]

2.—Irritation of the **renal nerves** is proved by histologic examination which shows the existence of degenerative lesions or simple irritations of the nerve fibers. **Renal edema**, as well as being of the nature of a dyscrasia, may also be a reflex nervous edema. The cases of hemianasarca consecutive to traumatic nephritis furnish an undoubted proof of this statement. This nervous action alone allows of an explanation of the character of the variability and the localization of the edema on one side of the body or in a special region, as is sometimes seen in cases of nephritis.

This nervous action is in the nature of a reflex stimulation of the vasomotor centers. Reflex edema is not confined to the kidney. It has been observed in cases in which the point of origin of the reflex producing the edema was the pleuropulmonary nerves and the uterine nervous plexus. This same nervous irritation may account for lumbar pains and the polyuria of cases of nephritis. It also is concerned in the pathogenesis of intermittent glycosuria, and to it also certain cases of sudden death supervening in the course of Bright's disease may be attributed. Opposed to the preceding symptoms, which are attributable entirely or partially to nervous action, it is convenient to place those that are manifestly the result of uremic intoxication. These are the nervous troubles, such as convulsions, delirium, coma, ocular and auditory troubles, nervous dyspnea of toxic origin, and finally gastrointestinal disorders. It is necessary to note, however, that the nervous action may intervene in the beginning in producing the congestive processes found in the nervous centers, the lungs, or the digestive apparatus. [J.M.S.]

3.—The results of experiments on animals show that **thiocol** has an antituberculous action in the animal organism and not merely a favorable effect on the general nutrition and on certain symptoms of tuberculosis. Experimental facts as well as clinical experience authorize the use of thiocol not only in **pulmonary tuberculosis** but also in other forms of tuberculous disease such as tuberculous pleuritis and tuberculous peritonitis. [J.M.S.]

Archives de Médecine des Enfants.

February, 1901. [Vol. iv, No. 2.]

1. A Case of Diphtheritic Stomatitis Due to Oöspora. A. TRAMBUSTI.
2. The Clinical Forms of Infantile Tuberculosis. A. MOUSSOUS.
3. A Severe Case of Atarepsia Neonatorum. BAUMEL and SCHREYER.
4. A Case of Tetany Occurring in Acute Enterocolitis. CHARLES LÉVY.
5. A Case of Adhesion of the Labia Minora. E. CAZAL.

1.—Trambusti reports a case of **stomatitis** occurring in a child of 3 years. The gums and roof of the palate were covered with an exudate in plates, looking exactly like diphtheria. The temperature remained high. Preparations examined bacteriologically gave quantities of filamentous microorganisms, and a few cocci, but no diphtheria bacilli. Beside a few colonies of staphylococci, the great number of colonies showed the filamentous masses, very like leptothrices, yet evidently **oöspora**. They were not pathogenic when inoculated into animals. Trambusti describes their actions upon different media, and suggests that other conditions, thus far attributed to leptothrices, as noma, etc., may be due to oöspora. [M.O.]

2.—In this article Moussous discusses **general tuberculosis** in young children. Tuberculosis before the third year is either thoracic or general, much more frequently the latter. While very few children of tubercular parents are born with tuberculosis, there are born many children with so debilitated a system that, if kept among tubercular people, they will inevitably develop consumption. The fact that they have a good chance of escaping this result, should they be at once removed from their tainted surroundings and brought up in the country, seems often forgotten, even by the medical profession. In healthy-looking children the disease may remain latent for weeks, as it is rarely seen before the third month of life. Whether hereditary or acquired, its course may be chronic or acute. **Chronic generalized tuberculosis** may be divided into 3 periods; first, a very short initial stage, with bronchitis or bronchopneumonia alone, or following an infectious disease, or gastroenteritis. Then, instead of recovering, the child remains ill, without fever, weak, with an ever-increasing cachexia. The spleen, liver, and general lymphatic system enlarge. This is the second stage, and lasts a long time. The last stage is death, occurring quietly in a few days. Or the disease may be complicated by pneumonia, Pott's disease, pleurisy, otitis, etc. It may last even up to 4 or 5 years, but generally only until the fifteenth month. **Acute miliary tuberculosis**, on the other hand, runs a rapid course, with high fever, diarrhea, enlarged spleen, tympany, bronchopneumonia,

etc., and death. But the chronic form may suddenly end with meningitic symptoms, either convulsions or hemiplegia, with death in from 2 to 4 days. After detailing the differential diagnosis between general tuberculosis and the many other infantile cachexias, Mousous speaks in high terms of the serum reaction as obtained by Bard, and hopes that this method of forming a positive diagnosis will soon be perfected. [M.O.]

3.—Baumel and Scheydt report the case of a child who first had convulsions when 1 month old. Stomatitis and constipation next appeared. Vomiting had always existed, though the wet-nurse nursed him regularly every 3 hours. The child was kept in an incubator, and given large doses of bromide and chloral. At 4 months the convulsions decreased in frequency, and the vomiting began to grow less. A month later the child went to the country cured. **At the age of 3 months, he had lost 680 grams. At 6 months he gained 62 grams daily for four days.** These weights show what a baby can lose and gain. [M.O.]

4.—Leroux reports the case of a boy of 2 years, with distinct tetany in the course of a severe acute enterocolitis. In spite of the frequency and severity of the convulsions, the child recovered. He showed no signs at all of rachitis. [M.O.]

5.—Cazal reports the case of a girl of 19 months, whose labia minora were adherent. A tiny opening for the passage of urine was seen just below the clitoris. As there had been no vulvitis, this condition must have been congenital. It was easily divided with very little bleeding. No dressing was necessary as it healed at once. The rest of the genitalia were found normal beneath. [M.O.]

Révue de Chirurgie.

February, 1901. [21me Année, No. 2.]

1. Peritonization in Laparotomy. E. QUÉNU and JUDET.
2. The Surgical Treatment of Purulent Peritonitis Following Perforation in Typhoid Fever. ED. LOISON.
3. Ligation of the Abdominal Aorta. P. TILLAUX and P. RICHE.
4. An Experimental Study of Fracture of the Upper Jaw. R. LE FORT.
5. The Study of Osteomalacia. G. GAYET and L. M. BONNET.
6. Chopart's Amputation. A. LA POINTE.
7. Torsion in Hydrosalpinx. F. CATHELIN.

1.—Quénu and Judet use the term **peritonization**, or **peritoneal autoplasty**, for their method of suturing the cut or torn ends of the peritoneum to the intestine, in operating, so that the intestines only touch the endothelium, and all raw surfaces have a serous covering. Besides, covering a denuded surface with peritoneum prevents exudation and hemorrhage, and further diminishes the possibility of infection. It also hinders the formation of adhesions, which are so often followed by intestinal occlusion. This method was first practised by Hegar, whose name it bears. It should be especially applied in laparotomy for appendicitis, salpingitis, ovarian cysts, and fibromata. The technic in each case is described, with 14 case histories. During 5 years they have performed 129 laparotomies with 5 deaths, 3.8%. When operation is done by this method, colicky pains rarely occur; drainage is necessary only from 2 to 4 days; and micturition and defecation are never affected. Nor do these patients, operated some time before, return with digestive disturbances, or abdominal pain. During these five years, only one case has developed postoperative intestinal occlusion. [M.O.]

2.—Though peritonitis may arise outside of a typhoid ulcer in the small intestine, the majority of cases follow perforation of such an ulcer. A diffuse, purulent peritonitis follows, fatal in 95%, in 3 to 6 days. Of the 90 cases of perforation surgically treated, which Loison has collected, 16 recovered, 21.6%. His own case is described in full. Perforation generally occurs in the second, third, or fourth weeks of the disease, and cases operated within 24 hours after the occurrence of perforation generally recover. But it is always difficult to diagnose positive perforation; the general condition of the patient may not warrant operation; the site of the perforation may not be found, or multiple perforations may exist. Loison describes laparotomy in such cases, when and how it should be performed, the method of finding and suturing the perforation, drainage, etc., in full. [M.O.]

5.—**Osteomalacia** is a disturbance of the nutrition of the bones, making it impossible for the bones to keep their lime salts, resulting in a softening of the skeleton. This disturbance of nutrition may be local or general. Local osteomalacia may be traumatic, infectious, or due to certain nervous affections. Traumatic osteomalacia is more frequent in the vertebral column, and the tibia; it is usually due to direct violence, and it is rather more common past middle age. Pain and softening follow rapidly. The infectious theory is not as yet positively proved, yet influenza, tuberculosis, and syphilis, probably, cause osteomalacia. The lesions found in osteomalacia are the same, whether the process be generalized or local. These lesions vary much, and show nothing specific. After discussing the various theories, and reporting 13 cases, Gayet and Bonnet conclude that different disturbances of the nervous system probably play an important role in the etiology of osteomalacia. A possible explanation of the good results following ovariectomy may rest in the fact that the ovarian secretion causes an active elimination of the phosphates, after the removal of which the softening gradually disappears. [M.O.]

Gazette Médicale de Paris.

February 9, 1901. [Vol. i, No. 6.]

1. The Winsum Skull, a Cranial Malformation. FERNAND DELISLE.

1.—This is a reply to Dr. Folmer's article upon the skull found at Winsum, in Holland, 20 years ago. Folmer considered it a macrocephalic head deformed artificially. Delisle, on the other hand, believes the skull to be a malformation. Its height is striking compared with its length and breadth. The frontal region slopes greatly and the occiput is almost vertical. A study of the sutures and the two teeth remaining lead to the conclusion that the individual, at the time of death, was over 30 years old. The synostosis of the sagittal and frontal sutures show malformation, and not deformity due to pressure. The bones of the top of the head had to give way as the brain grew beneath, especially as the bones were fast below. That explains the bulging of the upper part, just as in hydrocephalus. Besides, the frontal and temporal bones show no signs of pressure. Delisle considers the Winsum skull acrocephalic, a malformation due to development, the lower sutures having been obliterated, the head grew where it could. All the measurements of the skull are given. [M.O.]

Journal de Médecine de Bordeaux.

March 3, 1901. [31me Année, No. 9.]

1. A Case of Traumatic Hysteria. GUYOT and PERY.
2. Regeneration in the Liver. M. B. AUCHE.
3. A Case of Congenital Unilateral Microphthalmia. GINETOUS.

1.—Guyot and Pery report a case of **traumatic hysteria** in a girl of 13. A month ago she fell from a ladder, from a height of about 6 feet, striking upon her forehead. There was no loss of consciousness or convulsions. She was all right for 2 weeks, then during 2 or 3 days her cheeks became flabby, and trismus occurred. This condition of lockjaw persisted for 2 weeks. As she was a foundling, her ancestry was unknown. Paralysis of both branches of the facial nerve existed on the right side. At night, however, she shut her right eye too. There were found scattered areas of anesthesia and hypesthesia. The application of electricity cured the condition very quickly. Guyot and Pery comment upon the fact that the few cases of hysteria or neurasthenia reported in children, followed falls upon the head. A differential diagnosis is given between facial paralysis due to traumatism, or true facial paralysis, and that from traumatic hysteria. [M.O.]

2.—It has been shown by many experiments that when degeneration occurs in the liver, **the cells of the liver regenerate**, producing tissue to take the place of that destroyed. Chauffard says that **compensatory hypertrophy always occurs in the liver**. This is the condition ordinarily found in diffuse or nodular parenchymatous hypertrophy of the liver. In acute yellow atrophy, also, the regenerating cells are found in great numbers with those that have degenerated. When this regeneration exists in

very small amount, Chauffard calls it "radiate compensatory hypertrophy." This Auché found in a case of purulent angiocholitis and periangiocholitis, which is described in full. A case of congestion of the liver in heart disease is then detailed, in which regeneration of the liver-cells was observed. [M.O.]

3.—Ginestous reports the case of a child of 3 months, with **unilateral microphthalmia**. When the mother was 4 months pregnant, an older child kicked her violently in the abdomen. This hurt severely, but the pregnancy went on to term. At birth, the left side of the baby's face was still embryonic in character, the eye-lids being very small. When the baby opened its eyes, at 2 months, the left eye was the size of a small bean only. A congenital cataract existed also. The right eye was normal, as was the body, with the exception of a dermoid cyst under the tip of the tongue. Ginestous believes that the injury to the pregnant mother probably caused the occurrence of the unilateral microphthalmia. [M.O.]

5. On the Injection of Sodium Cinnamylate (Natri cinnamyl-lic) in Tuberculous Patients. L. A. FINKELSTEIN.

1.—Will be abstracted when completed.

2.—Popelsky takes up the polemic incited by Dr. Gertsen (See *Vratch*, Vol. xxii, No. 11, recently abstracted in the PHILADELPHIA MEDICAL JOURNAL) and devotes a lengthy article to the exposition of the fallacies with which Gertsen's experiments were surrounded and the erroneous conclusions deduced from them. He claims that his experiments were performed strictly in accordance with the directions given by Schiff, and that they prove only one thing, namely, that Schiff's theory, modified by Gertsen, is wrong. The spleen, according to his observations, has no specific effect on the formation of trypsin. The results obtained by Schiff, Gertsen, Pachon, and Gachet the author explains in the following manner: It has been demonstrated that there exist in the organism bodies in the nature of ferments, possessing oxidizing properties. These bodies are present in the formative elements of the blood and are derived mainly from the destruction of leukocytes. Their presence, therefore, in the spleen is due to the blood and not to the splenic tissue *per se*. During the height of digestion digestive leukocytosis takes place; in other words, an increased destruction of the leukocytes and consequently an increased formation of these oxidizing bodies, the latter aiding in the oxidation of the protrypsin into trypsin—hence the fact that a swollen or hyperhemic spleen is concomitant with an increased formation of trypsin. [A.R.]

3.—Wolfson points out the impossibility of isolating those cases of diphtheria in which a brief attack of sore throat is followed by complete recovery, and yet the diphtheria bacilli persist for a long time, rendering the hosts a menace to the public. The following cases are cited as illustrations: A woman suffered from a slight sore throat without any glandular involvement. On the third day the throat was clear and the temperature normal. A bacteriologic examination, repeated 3 times, showed the presence of diphtheria bacilli. The patient could not be kept in her room for more than a week. She went to concerts, made calls, etc. In another case the daughter of a physician engaged to be married to a physician had an attack of mild sore throat a few days before the wedding was to take place. A bacteriologic examination showed the presence of diphtheria bacilli. On the fourth day the patient was perfectly well. She refused to be isolated or postpone the wedding. In another family, two children took sick with diphtheria and were sent to the hospital. The throats of the other members of the family were examined and diphtheria bacilli found. No isolation was permitted.

The fourth case is of special interest. A servant, 23 years old, had an attack of diphtheria while nursing her diphtheritic child in a foundling asylum. She kept her affection secret, and 2 weeks later, after the child died of laryngeal diphtheria, came to the author, presenting postdiphtheritic paralysis of the palate. A bacteriologic examination disclosed the presence of diphtheria bacilli. The latter persisted for a period of 13 months, and were still to be found at the present writing. However, while morphologically they were proven to be true Klebs-Löffler bacilli, they were found avirulent on two different occasions, when inoculated into guineapigs. The author emphasizes the importance of using local antiseptics, believing that in cases in which the bacilli persist in the completely recovered or the healthy, the persons may be allowed to go about, providing they observe the same precautions with regard to expectoration, utensils, etc., as are recommended in tuberculosis. [A.R.]

5.—Finkelstein devotes an extensive paper to the subject of the effect of cinnamyllic acid or its salts on tuberculosis. After a thorough review of the subject, quoting *in extenso* the observations of others *pro* and *con*, he reports his own observation made in the sanitarium for consumptives. In all 20 cases were studied. The history of each is given, but the cardinal points, as well as the results of the treatment, are summarized as follows: 1. The ages of the patients varied from 19 to 42, the majority from 20 to 30. 2. One of the patients was at the time of admission in the first stage of the disease, the other in the second. By the "first stage" the author understands a condition in which one or both apices, not below the second rib, are affected, and there is no catarrh. In the "second stage" there are marked changes accompanied by catarrh, but without any signs of destruction of lung-tissue. 3. The number of injections was from 10 to 45. 4. The duration during which the injections were made was from 1 to 5½ months. The duration of the observations made prior to the injections was from 10 days to 14½ months. 5. The cough diminished during the injections in 5 patients, in 11 it remained as before, in 4 it became either worse or better. Prior to the injections it diminished in 14, remained stationary in 2, and was either better or worse in 4. 6. The sputum has undergone no change, either in quality or quantity, in 16; in 2 it became less, in 1 more profuse and in 1 lighter in consistency. Prior to the injections it became less in 9, remained stationary in 8, changed in character in 2 and was irregular in 1. 7. The tubercle bacilli remained as before in 13, became less in number in 3 and increased in 4. 8. No special improvement of the subjective symptoms was noticed during the injections. 9. The night-sweats disappeared also before the injections. Only in one case did they disappear during the treatment, while in the other they persisted in spite of it. 10. The weight was reduced in 4; in the other it increased from ½ to 37½ pounds. Prior to the treatment it was decreased in 3 and increased from 1½ to 43 pounds in the others. 11. The enlarged lymphatic glands remained as before. In 1 patient with a fistula of a lymphatic gland the opening did not close. 12. In 1 patient with laryngeal tuberculosis an improvement was observed during the injections, but this improvement is to be credited more to the general hygienic and dietetic treatment than to the sodium cinnamylate. A number of similar cases improved in the sanitarium prior to the use of this drug, and many even recovered. 13. The areas of dulness did not diminish during the injections. On the contrary, in 2 cases the tympanic sound reappeared. 14. In 1 case the breathing became weaker, in 2 it changed from bronchial, and in 1 from weak to amphoric. In 2 it assumed a marked bronchial character, and only in 1 did it become less raspy. In all others the conditions remained the same. 15. Two patients had hemoptysis twice (1 had it twice prior to the injections, the other 4 times). In 1 case hemoptysis occurred once, in the other 5 times prior to the injections, but in neither case was blood found in the sputum during the treatment. 16. The treatment exerted no influence on the temperature. 17. In 1 patient somnolence was observed for from half to one hour after the injection. It thus appears that the results obtained could not be considered either favorable or encouraging. The slight improvement which took place in some of the cases could be very well attributed to general treatment and other favorable conditions under which the patients in sanatoria are placed. The best that could be said about this drug is that it did no harm. [A.R.]

THE PROPHYLAXIS OF VENEREAL DISEASES.

Medical Aspects of the Social Evil in New York.*

By PRINCE A. MORROW, M.D.,
of New York.

Attending Surgeon to the City Hospital, Attending Physician to the Department of Skin and Venereal Diseases, New York Hospital, etc.

It would hardly seem necessary in a paper before a learned society of medical men to pass in review the pathological significance of the class of diseases comprehended under the general term—venereal—or the important relations which these diseases bear to the public health.

There is reason to believe, however, that the enormous extent to which these diseases prevail and their far-reaching and pernicious influence upon the health of the community are not sufficiently appreciated by the general profession. Unfortunately, our perceptions of the significance of certain evils become blunted by habituation, and we accept them as natural and among the established order of things.

While we view with lively concern those epidemic waves of disease which from time to time sweep over the community, we are apt to regard with indifference, diseases which are of common occurrence and exist in a state of permanence in our midst. We take alarm and employ active means of defense against the threatened invasion of the cholera, the plague, yellow fever, etc., while we are insensible to the ravages of a disease—syphilis—which is vastly more destructive to the health of the community than all the foreign pestilences that have visited our shores.

It has been estimated by a competent and careful authority that fully one-eighth of all human suffering is caused by venereal diseases or their sequelæ. As regards their prevalence in this city it may be said that there are no data upon which we can base conclusions possessing definite scientific value. Venereal statistics cannot be computed by the methods ordinarily employed for the detection and registration of diseases. Unfortunately, they belong to the category of "shameful diseases," the avowal of which would, to employ a legal phrase, tend "to incriminate or degrade the bearer," so that the actual number of such cases in any city or community must always remain an unknown and unknowable quantity.

It is well known that material as well as moral and sanitary conditions modify venereal morbidity; it is much larger among urban than among rural populations. Then again, even in our large centers of population oscillations occur just as in other current diseases, the explanation of which escapes us.

According to Neisser, the discoverer of the gonococcus, gonorrhea is with the exception, perhaps, of measles, the most universal and widespread of all diseases. Other German authorities have computed that fully three-quarters of the adult male population and one-sixth or more of adult females have contracted gonorrhea.

As regards the prevalence of syphilis, Fournier found in careful personal investigations, extending over a number of years, of the general hospitals of Paris from 15% to 23% cases of syphilitic origin. From these figures,

taken in connection with the enormous number treated in the special hospitals, in dispensaries and in private practice, he estimates that one-seventh of the population of Paris is syphilitic. When we consider the cosmopolitan character of the population of New York, the large foreign colonies of Bohemians, Italians, Russian and Polish Jews, many of whom bring their social vices and sordid, communistic modes of living, it is quite possible that Fournier's figures, with some modification, may apply to this city as well as Paris.

The following statistics of five of the principal dispensaries in New York City give some idea of the proportion of venereal morbidity to general diseases.

The records of the out-patient departments of the following hospitals for 1900 show:

The New York Hospital, total number.....	11,550
Number of venereal cases.....	1,054
The Vanderbilt Clinic, total number.....	48,967
Number of venereal cases.....	2,935
New York Dispensary, total number of cases	42,531
Number of venereal cases.....	3,895
The Good Samaritan Dispensary, total number	86,916
Surgical and venereal cases.....	20,530
(25 to 50% venereal.)	
Bellevue Out-Patient Department.....	67,470
Venereal cases.....	7,320

Averaging all together nearly 10% of venereal cases.

These figures by no means represent the actual number of cases of venereal disease, as a large proportion of the cases treated in the skin departments were syphilodermata.

Furthermore, venereal cases undoubtedly furnish a certain contingent of the classes in the eye, throat, gynecological and other departments.

It is not claimed that these few statistical data afford any correct indication of the amount of venereal morbidity in this city, they simply show that it exists to a larger extent perhaps than is generally realized.

Venereal morbidity may best be studied in taking large bodies of men, such as the army and navy, where every case of disease is carefully tabulated and the results analyzed. To take an extreme case, Sir H. S. Cunningham's report of the health of the British Army in India for the year 1895 shows that out of 68,331 British soldiers stationed in India, the admissions to the hospital for venereal diseases were no less than 36,881 cases, or 53.7%. Of these 17,702, or 25.9%, were cases of syphilis. During this year 15 died from syphilis, 348 were invalided and 130 finally discharged as unfit for service from the same cause. Of economic interest is the fact that these diseases occasioned a loss of 1,155,451 days of active service.

These figures did not in the opinion of the official experts represent the whole amount of venereal diseases, many cases being treated without admission to the hospitals. Moreover, the report shows that of the entire army in India, 13,000 of whom are annually sent home to England, 25% were syphilitic. It is to be hoped that of our returning forces from the Philippines, no such percentage will bring back syphilis as a souvenir of their sojourn in these islands.

While venereal diseases are rarely fatal in their immediate effects, yet in their remote consequences they contribute largely to the bills of mortality. Our mortality statistics throw a misleading light upon the mortality from these diseases. The deaths from the sequelæ of gonorrhea are rarely referred to their true etiological factor. The deaths from syphilis are conveniently grouped under affections of the viscera, diseases of the

* Read before the New York County Medical Society, February 25, 1901.

brain, cord, liver, etc., while the determining cause is chastely concealed.

GONORRHEA.

In the estimation of the laity the relations of gonorrhea to the public health would be regarded as of no more significance than a catarrhal inflammation of any other mucous membrane, and, less than a quarter of a century ago, this opinion would, perhaps, have been shared by many medical men. But within recent years our conception of the pathological import of gonorrhea has been singularly amplified, not only as regards its chronicity, but especially its etiological relationship to many morbid states of the general system. To-day we recognize it not only as the most widespread but also as one of the most serious of infective diseases; it has risen to the dignity of a public peril.

Since the discovery of the gonococcus, new facts have been developed showing that instead of being limited to the genito-urinary tract the range of its morbid action is much more extensive and, not infrequently, is radiated to important visceral organs. Staining and culture experiments have demonstrated its presence, not only in the ovaries, tubes and peritoneal cavity, but also in the pleura, the endocardium and pericardium, the bloodvessels, joints and tendon-sheaths, etc. Moreover, it has been demonstrated that it stands in the relation of causal factor to visceral lesions which often terminate fatally. An analysis of the recent literature of the subject shows a surprisingly large number of such fatal complications.

I will pass over briefly the common complications of gonorrhea, the affections of glandular structures, the acute and chronic inflammations of the prostate and bladder, of the seminal ducts and vesicles, the cord, epididymis, testes, etc. These latter affections are most important, as they may entirely destroy the fecundating capacity of the individual. The sequelae of gonorrhea, stricture and ascending inflammations of the ureters and kidney causing pyelitis, etc., which not only seriously compromise the health but may endanger the life of the individual, need only be mentioned.

In the female, the local and general effects of gonorrhea are apt to be much more serious and permanent owing to the extent and character of the structures exposed. In addition to vaginitis and vulvitis, the virus may penetrate the uterine cavity with resulting endometritis, ascend the tubes, causing painful and suppurative swellings, with acute exacerbations not infrequently necessitating laparotomy. Most cases of salpingitis must be classed as gonorrheal. Sanger found that about one-eighth of all his gynecological cases were due to gonorrheal infection. As more permanent results may be mentioned chronic inflammation of the uterus and its adnexes, resulting in fixation of these organs, various disorders of menstruation, anemia, neurasthenia, etc. German authorities state that 80% of all deaths from diseases of the uterus and its adnexes are of gonorrheal origin.

The virus spreading through the lymph and vascular channels may cause generalized metastases. General septicemia and pyemia from foci of suppuration in the genito-urinary tract are by no means uncommon.

Many other grave manifestations of gonorrhea in both sexes might be referred to, such as its frequently destructive effect upon the sight from inoculation of the child at birth. Blennorrhea neonatorum contributes a large contingent to our blind asylums, estimated from

10 to 20%; from 40 to 60% before the Credé method was instituted. Neisser thinks that of the 30,000 blind in Germany from this cause, a large proportion might have been saved by the employment of this prophylactic measure. The prominent role which the gonococcus plays in the etiology of joint-affections of a serious and intractable character should not be overlooked.

It is, however, the destructive effect of gonorrhea upon the procreative functions that I would especially emphasize as of interest in this connection. Neisser contends that gonorrhea is a more potent factor in the depopulation of countries than syphilis even. He regards gonorrheal infection of the male responsible for 30% of sterile marriages. Busch, Fürbringer and others have demonstrated that 90% of all cases of azoospermia may be traced to antecedent inflammation of the epididymis and cord.

A percentage variously estimated at from 40 to 80% of endo-, meso-, and perimetritis is of gonorrheal origin and a cause of sterility in women. Noeggerath found in 81 gonorrheal women, 49 entirely sterile. In 96 sterile marriages Kehrner found 30% due to azoospermia, 33% to perimetritic inflammatory changes, 8.3% to amenorrhea, 4.1 to vaginismus—all of gonorrheal origin.

SYPHILIS.

Syphilis, as we comprehend it to-day, has a much graver significance in its relation to the public health than was formerly supposed; not that the disease exhibits a severer type, but that its pathological domain has been greatly enlarged with our increased knowledge of the vast number, the complexity, and the far-reaching character of its morbid processes. That our conception of syphilis has entirely changed will be evident from comparing the older textbooks with a modern treatise on syphilis. In the former almost the entire symptomatology of the disease was made up of the visible accidents on the external surface of the body and for the cure of which a few months' treatment was all that was deemed essential. In the modern treatises these surface accidents are considered of subsidiary importance, as they rarely affect the integrity of any important organ, while the visceral determinations of the disease, the cerebral, spinal, vascular, ocular, articular, pulmonary, intestinal, hepatic and renal affections constitute its chief significance. We now recognize that the infection of syphilis is of a more profound and permanent character, that it may affect every constituent element of the body, and that these systemic complications are serious and often fatal.

Of the tertiary determinations syphilis of the brain and cord occupies the first rank in frequency as well as gravity. Fournier declares that the nervous system is the preferred victim of tertiarism. His personal statistics, extending over a period of 39 years, and embracing 4,000 cases of tertiary syphilis, show that next to the skin the brain and cord were the organs most frequently affected. The cutaneous accidents number 1,145, while affections of the brain number 758; of the spinal cord 1,098; giving a total of 1,857 cases in which the brain and cord were involved.

It is interesting to note that 354 of these cases of cerebral syphilis were followed up to a known termination; 77 were cured; 68 died, while the remaining 209 survived, but with various infirmities of a grave character and in every case irremediable.

Want of space forbids the mention of the almost

innumerable manifestations of syphilis. Among them may be classed oculomotor paralyses, hemiplegia, paraplegia, epilepsy, chorea, multiple neuritis, progressive muscular atrophy, locomotor ataxia, general paralysis, etc.

We come now to consider certain irradiations of syphilis which constitute a grave social danger and which emphasize the importance of prophylaxis from a humane as well as a sanitary standpoint. I refer to *syphilis insontium*, or syphilis of the innocents. Unfortunately, the risks of this disease are by no means limited to the offender against morality, but are transmitted to innocent wives and helpless children by its introduction into the family. The infected wife is not only made to incur all the individual risks we have been considering, which in her case are much greater as she is most often ignorant of the nature of her disease and does not receive the benefit of prompt and efficient treatment. Incredible as it may appear, many husbands who infect their wives employ every possible means to prevent them consulting a physician from a fear of the detection of their infidelity which would come from the woman's knowledge of the nature of the trouble.

The frequency of marital syphilis, the enormous extent to which it prevails, is not generally known or even suspected. Fournier's statistics embracing only those cases in which the origin of the infection could be positively traced, show that out of every 100 syphilitic women 19, or nearly 5%, are conjugally contaminated.

During the past year I have carefully investigated the origin of the infection in every syphilitic woman who applied for treatment in my service at the New York Hospital. Fully 90% were enrolled as married women. Excluding all cases in which there was a suspicion of irregularity, and including only those in which the statement of the woman that she lived with and was supported by her husband was borne out by every appearance of truth, fully 70% appeared to be cases of conjugal infection. This percentage is large, but it will be remembered that few public women come to this hospital for treatment.

The number of cases of syphilis insontium is not to be measured by the number of victims of marital syphilis. Innocent inoculations occur in the daily occupations and intercourse of life. Infection of children and other members of a family take place in the thousand and one intimacies of family life, children infect their nurses and nurses contaminate children.

The irradiations of syphilis can be traced not only through the family, but through various industrial occupations and professional relations. Professional syphilis, that of physicians, surgeons, and accoucheurs, is vastly more common than generally supposed; more than 50 such cases have come under my personal observation. We hear little of them, as the victims have every motive to conceal the nature of their trouble.

The hereditary consequences of this disease will be only briefly referred to. Syphilis stands as the perfected type of an hereditary disease. No other disease is so susceptible of hereditary transmission, nor so pronounced in its effects, and fatal to the offspring. Statistics show that from 60 to 86% of all syphilitic pregnancies terminate in death *in utero*, or stillborn children. Of children born alive and viable, a large proportion of those who survive the first year suffer from a category of infirmities which can only be briefly recapitulated. Dystrophies and degenerations, cranial and nasal mal-

formations, hydrocephalus, osseous lesions, various affections of the brain and cord, lesions of the organs of special sense, deaf-mutism, idiocy, etc. Rickets has its almost exclusive etiology in syphilis. The predisposition to abortion may be manifest in the third generation. From the statistics of Pinard, Gibert, Tarnowsky, and others, we find that of 81 pregnancies occurring in households in which one of the parents had inherited syphilis, there were 28 abortions, 13 stillborn, 7 died soon after birth, while only 33 finally survived.

The social misery caused by venereal diseases cannot be overlooked; the separations, divorces, the breaking up of families, the dishonor of children, are deplorable consequences which can be too often traced to the introduction of these diseases into the family.

We have thus seen that there exists in our midst a large and important class of diseases which have the most intimate relations to the public health; they entail suffering, they destroy life, they are the fruitful source of a vast deal of social misery. In addition they have important socio-economic relations in their incapacitating effect upon the wage-earner, army and navy invalidism, and also in their undoubted influence as a factor in the depopulation of countries. No disease has such a devitalizing influence upon the procreative function as gonorrhea, no disease has such a murderous influence upon the offspring as syphilis, they literally poison the fountains of life.

In passing, one distinctive peculiarity of venereal diseases may be referred to. The germs of many infectious diseases cannot be guarded against, the recipient is a passive victim; infection is inevitable. The contagion of venereal diseases, exception being made of accidental inoculations, is always evitable; it is effected by the voluntary act of individuals. The communication of venereal disease is therefore to a certain degree wilful.

PROPHYLAXIS.

We cannot well consider the prophylaxis of any disease without reference to our sanitary authorities who are the accredited representatives of the State in all matters relating to the protection of the public health. At the present day the extermination of every contagious disease is the watchword of sanitary science. In an address before the Congress of American Physicians and Surgeons, in 1894, a high Government official proclaimed "that the controlling movement, so far as medical science is concerned, which will mark the closing of the present century and the beginning of the next, is the settled resolution to exterminate every contagious disease." And yet the dawn of the twentieth century witnesses the spectacle of a large class of diseases, dangerous to the public health, confessedly contagious, essentially evitable, and yet absolutely ignored by our sanitary authorities. There is not a single city or community in the United States in which these diseases are subject to sanitary supervision.

We may ask why this apparent indifference, this absolute inaction upon the part of the guardians of the public health? Is it from the traditional conception that these diseases do not come within the legitimate sphere of preventive medicine? But at the present day our sanitarians do not restrict their work upon approved traditional lines, they are constantly enlarging the sphere of its application. They have attacked the modern Sampson of tuberculosis upon the grounds of its contagiousness, but the syphilitic is 20 times more active as a spreader of contagion than the consumptive.

Is it from a conviction that since these diseases are commonly due to voluntary exposure they are in a certain sense *merited* and that society is under no obligation to protect those who are able to protect themselves? But is it not the manifest duty of society to protect the army of innocents who are infected through no fault of their own? Besides, the large proportion of the victims of venereal disease are not the seasoned sinners, the confirmed debauchees, but the young, the immature, and the inexperienced. An analysis of statistics shows that the average at which syphilis is contracted by women is from 18 to 20, in men from 20 to 25.

Is it not rather true that this policy of inaction is a confession of inability to cope with the evil by any methods known to sanitary science?

We must admit that the sanitary control of venereal diseases is much more difficult than would at first appear; the problem is so complicated by the nature of the cause and the mode of contagion, so interwoven with questions of infringement of private rights, restrictions of individual liberty, and, finally, with questions of morality, that there appears no clear way in which the evil can be touched by the strong hand of repression.

Undoubtedly the chief obstacle to sanitary intervention in this country is the inhibitory influence of public sentiment against the legal recognition or license of prostitution.

Prostitution is the *fons et origo*—the baleful source of the diseases under consideration. While not directly concerned in the transmission of syphilis in the family, it is the fountain head to which all innocent inoculations may be traced. Hence the suppression of prostitution and the prevention of venereal diseases are indissolubly linked.

But the suppression of prostitution is a Utopian idea. It has existed in all ages and under all conditions of civilization. The most severe and drastic measures carried out under the most despotic authority have failed to crush it. Almost every conceivable punishment, flogging, branding, shaving the head, banishment and death have been employed in vain. It cannot be annihilated by force. In the existing economic and moral conditions of society it is a necessary evil, not in the sense of being indispensable, but inevitable.

Now the law takes cognizance of certain forms of prostitution. It has made the keeping of disorderly houses a crime; it has made open public provocation a misdemeanor. It can sentence the keeper of a brothel to the penitentiary, it can send the inmates to the workhouse; but the law has its limitations. There are certain forms of the evil which are intangible, the prostitute can solicit in the streets by signs, which though subtle are no less significant than the voiced invitation. She can make whatever disposition she pleases of her body in her private apartments, and in this stronghold of individual liberty the law cannot touch her.

In this city the crusades against vice have been too often campaigns of force. From time to time a cry of alarm is raised against the public peril created by the appalling conditions of the social evil in certain localities. The strong arm of the law is invoked, the police are stimulated to do their duty, and the city is declared purified. Such a movement took place five or six years ago, but the ultimate result of the harsh and punitive measures employed was simply to disperse and scatter the evil, which was comparatively isolated in certain quarters. Unfortunately, dissemination is not destruc-

tion. From an exclusively medical standpoint, segregation represents the least objectionable form of the social evil. To change the *locale* of a shameless traffic from one precinct to another, to drive it to Harlem, or even to Hoboken, is not to break it up. The inmates of disorderly houses when turned into the streets are confronted by the stern necessity of living. They carry in their depraved and often diseased bodies their only means of subsistence—they simply ply their demoralizing trade elsewhere. These crusades can make vice less flagrant, less scandalous; they can render the streets more orderly and more decent; but the volume of vice is not diminished—it is simply directed into other channels. Too often it takes refuge in the crowded tenements of the poor, or in the apartment-houses of the better class, and becomes a co-dweller with virtue and respectability.

Violent measures must always defeat the object in view, because they are of necessity intermittent and spasmodic. Violence is incompatible with the sustained and continuous effort required to combat this evil. The social reformer can accomplish more by measures for the amelioration of the social condition of women; by throwing stronger safeguards around minors, especially the orphans and unprotected; by establishing homes for the reception and reclaiming of fallen women; and by furnishing means and opportunities for the rehabilitation of those wishing to reform.

While the most stringent legislation can never accomplish social reforms, yet the arm of the law may be effectively invoked in preventing scandalous public provocation; in suppressing the affluents of vice—the wine-shops, low concert and dance-halls, and other disreputable resorts; in making the punishment for the seduction of minors more sweeping by raising the age of consent to 21 years; and by meting out the severest punishment against the purveyors of vice—men and women who make a trade of dealing in human flesh by enticing and selling into the slavery of prostitution innocent and unprotected young women.

REGULATION OF PROSTITUTION.

Recognizing prostitution not only as an ineradicable feature of our social order, but as a fruitful source of disease, what are the best methods of dealing with it from the standpoint of public hygiene? The system known as the "Regulation of Prostitution" has been tried in various countries of Europe. It is now in force in France, Belgium, Germany, Austro-Hungary, Russia, Spain and Portugal. It was introduced in England in 1860 and abandoned in 1881. In Norway it was tried from 1860 to 1888. In Switzerland it has been abolished in many communes, but still exists in Geneva. It was introduced in Italy in 1860, suppressed in 1888, and reestablished in 1891.

In all these countries the system is essentially the same with slight modifications. It has for its essential features the registration or inscription of all prostitutes that can be brought within the jurisdiction of the police, and the medical examination of these women at stated intervals. Any woman found suffering from venereal disease is sent to the hospital, where she is forcibly detained until the contagious accidents are cured. The object is to hygienize an insalubrious occupation by the retiring from circulation of all sources of contagion. Men are not subjected to surveillance. The only plea for this discrimination is that the woman who sells her body for money is engaged in a commerce or

traffic, and that the interests of public hygiene demand that what she offers for sale should not be tainted or contaminating to health. Besides, as the woman is the more active spreader of disease, she is the greater offender.

Like any other system, its value depends upon the thoroughness with which it is organized and the activity and energy with which its regulations are carried out. A number of statistics might be cited to show that the regulation of prostitution has an undoubted influence in limiting the dissemination of disease, such for example as the vastly larger proportions of cases of contagion that can be traced to the unregistered prostitutes who are not subjected to surveillance. Without reference to statistics it stands to reason that a public woman who is diseased will almost inevitably infect every comer, it may be four or five a night, while if she is quarantined in a hospital, so many men will escape. The more public women that can be brought under the operation of this measure, the more sources of contagion will be suppressed and the greater the protection of the public.

But right here comes in the limitation of its usefulness. Women do not like to be registered as prostitutes, they do not willingly submit to medical examination, they have a horror of imprisonment in a hospital. The result is they abandon public houses and become clandestine prostitutes, so that the *maisons de tolerance* in which vice is collective and centralized and can be most effectively supervised and controlled are in process of extinction.

In Paris the number of such houses has diminished from 250 to less than 40, although within this time the population has quadrupled. In Marseilles there were in 1875, 120 brothels with 600 inmates, 20 years later there were only 12 with 90 inmates. In Bordeaux the number has decreased from 60 to 21, and so in all cities where regulation has been enforced. Regulation has conclusively demonstrated that the surest way to break up disorderly houses is to subject them to sanitary surveillance. But with the passing of the brothels, there have sprung up hundreds of houses of rendezvous, in which public women do not reside, but to which they go when sent for. Vice takes refuge in theaters, music halls, dance halls, it seeks cover in private lodgings. The industry simply changes its form and methods of business; it becomes clandestine, more elusive, less susceptible of control and infinitely more dangerous to the public health.

To my mind one objection to this system is that it takes cognizance of only one factor in the spread of disease. It is a rank inequality of justice to subject the female offender to surveillance and allow the equally guilty male spreader of contagion to go free. Another objection is the inquisitorial character of this surveillance; moreover, when the police are armed with discretionary power, in the matter of arrests, they are apt to abuse this authority.

In countries where regulation is employed it has its partisans and opponents. While generally sustained by the medical profession it is condemned by others as defective and inefficient. The most violent opposition comes from the religious and moral elements of society on the ground that in hygienizing prostitution by sterilizing sources of contagion, it is rendered safe, and that this safety, however illusory it may prove, is a direct incitement, a provocation to debauch.

Without confuting the fallacy of this charge it may

be said that it is unfortunate that there should be such an irreconcilable conflict of opinion between the hygienist and the moralist upon this important question. The medical man and the moralist are both interested in the correction of the social evil. Instead of working independently, and often antagonistically, there should be cooperation and concert of action. The former looks only upon the *effects* of prostitution, the diseases it engenders, to prevent which appears to him the paramount issue. The moralist looks upon the social evil as a vice, an offence against morality, which should be combated by moral means alone.

Whatever may be the value of the system of regulation, as employed in Continental Europe, it is safe to say that it cannot be utilized in this country. Public opinion, which often has a force quite irrespective of its merits, forbids its establishment in this country, on the ground that it is equivalent to a licensing of vice. The experiment has been tried but once in the United States. In 1872 the Missouri Legislature enacted a law for the regulation of prostitution, modeled on the Continental plan. The system was introduced in St. Louis, but was in operation scarcely over a year when the obnoxious law was swept from the statute-books by an avalanche of protests, principally from women and the clergy.

Again, regulation is impracticable in this city, because the conditions essential to its successful application and working are wanting. This sanitary scheme contemplates the hospitalization of diseased public women and their quarantine during a period more or less prolonged, certainly until their contagious accidents are cured. Now, incredible as it may appear, there are not hospital accommodations for one in 2000 of the prostitutes in this city. The great city of New York provides for the reception and treatment of women suffering from venereal diseases just 26 beds in the City Hospital on Blackwell's Island. There is not a single hospital on Manhattan Island where a syphilitic woman, whether she be a prostitute or an innocent victim of the disease, may be treated. She may be received in Bellevue Hospital, but she is promptly transported to the Island.

Such is the situation. Prostitution, the root of the evil, cannot be extirpated, it will continue to bring forth its crop of dangerous diseases; any proposition for their prevention, based upon the regulation of prostitution, is impracticable. Can nothing be done to restrict or limit their spread?

PROPHYLAXIS BY TREATMENT.

What has been termed prophylaxis by treatment, appears to be the only practicable measure. In dealing with diseases in which there has been a comparative failure of the sanitary measures employed for their prophylaxis the value of treatment becomes magnified in importance. In the case of inoculable diseases, treatment constitutes the best prophylaxis, by sterilizing sources of contagion and limiting the period of their contagious activity. Prophylaxis by treatment is by no means a new idea. It was advocated as the only solution of the problem in the article on "The Relations of Syphilis to the Public Health" (Morrow's System, Vol. II, Syphilology, 1894). Its value and possibilities have been since more fully elaborated by Fournier, Barthelèmy and others.

Indeed the basic principle of any system of regulation is to hospitalize and treat as many sources of contagion as possible. Its chief defect lies in the fact that

the number of cases which can be subjected to treatment is limited. The feature of forced detention in a hospital excites an invincible repugnance. Treatment should be free and patients allowed to come and go at their will. Experience proves that more patients can be treated by liberty than by force, and the more patients we can treat the greater the protection to the public health.

Now it is a notorious fact that the vast majority of syphilitics do not receive proper treatment, not one in 20, certainly not one in 10 receives a treatment sufficiently prolonged. Statistics show that the larger proportion of the dreaded accidents of tertiarism occurs in this class of cases.

Reference has already been made to the lack of hospital accommodations for female venereals in this city. A slightly more generous provision is made for men. There are 56 beds in the male venereal wards of the City Hospital and a small number in the Metropolitan Hospital. This provision is notoriously inadequate. What is needed is the removal of the ban of ostracism which dishonors this class of diseases. Venereal patients should not be discriminated against. Admit that we owe no duty to the debauchees, but if society cannot protect the innocent from contamination, it owes them at least the recompense of free and skillful treatment. Moreover, morality should not qualify disease, medical science is sufficiently broad, charitable and humane to ignore such a petty qualification. The plea that these diseases are excluded from all general hospitals in this city on the ground that they are "contagious diseases" is a mere pretext. They are contagious only by inoculative contact, and in no hospital conducted on modern aseptic principles can there be any chance of contagion in this way. I would urge then that every general hospital in this city, receiving State or municipal assistance, should be required to open its doors to this class of diseases. Special wards or services should be organized for their reception and treatment.

Free hospital treatment is but one of the agencies and by no means the most important for the suppression of sources of contagion. Its application is limited to a small number and for a brief period. The contagious activity of venereal diseases is manifest during a long period, that of syphilis for two or three years. The large proportion of syphilitics are ambulatory cases, they do not require hospital care, they are quite able to go about and attend to their duties and employment. What they require is the prolonged treatment which the well-to-do syphilitic can procure at the office of his physician.

There are seven dispensaries in this city in which there is a venereal or genito-urinary service; in addition there are a few cases treated in the Harlem and Fordham Hospital dispensaries. There are ten others in which there is a skin or dermatological class in which, presumably, the syphilodermata may be treated. The dispensaries with venereal services should be multiplied. They should be located in convenient quarters of the city, readily accessible, so as not to involve too much loss of time to the patients in going and coming. Loss of time means to many patients the alternative of losing their employment or giving up treatment. Night classes should be established for patients unable to come during the regular day hours. In the surgical night class of the New York Hospital when these cases are admitted more than 70% are venereal.

These services should be organized and conducted with especial reference to the nature of the disease, due regard being had to the fact that the patient, whatever may be his position in the social scale is conscious that he has a shameful disease, the avowal of which is more or less humiliating; especially is this the case with women. These services should be conducted with all the privacy possible. There should be separate rooms for women. Time and time again innocently infected women have declared that they could not continue their attendance at my class because their entrance into this particular room, in which men are also received, would convict them of having a shameful disease.

These cases should be treated not only with reference to the individual risks of the patient, but with the cardinal consideration in view that every case is a focus for the spread of disease; and that measures of prophylaxis are quite as important as the cure of the disease. With the object of suppressing as promptly as possible all sources of contagion, the now obsolete practice of destructive cauterization of venereal sores, and the excision of chancres, whenever practicable, should be revived. Mucous patches which, with the chancre, constitute the almost exclusive sources of contagion should be subjected to the same sterilizing medication. For years I have employed the acid nitrate of mercury for this purpose.

Conjoined with the enlarged and improved facilities for treatment there should be a campaign of education. Patients should in every case be enlightened not only as to their individual risks but the risks they convey to others and the necessity of prolonged treatment. Time and time again patients who have infected their wives and children with syphilis have declared to me, with every indication of honesty as well as remorse, "I thought that I was cured; I did not dream that there was any danger." Now the average patient is ignorant of the varied and multiple modes of syphilitic contagion, and it is the duty of the physician to instruct him. In public practice this is difficult. A dispensary physician who sees from 50 to 60 patients or more in two hours cannot give the necessary time for such instruction. The same plan that is employed in many foreign clinics should be adopted here, viz., each syphilitic patient should be handed a printed slip, stating, in plain language, the nature of the disease, the modes of contagion, the risks of personal contact from erosions or mucous patches, the possible contamination of household articles, towels, spoons, drinking utensils, etc., the risks of hereditary transmission and also emphasize the necessity of thorough treatment.

The gonorrheal patients should be instructed as to the details of the technic to be employed in local treatment, the possible gravity of the disease, the danger of contagion even when the discharge may have apparently ceased, the significance of shreds in the urine as an indication that the disease, though latent, is still uncured, etc.

Physicians should never sanction marriage until all possible danger of infection is passed. Too much care and circumspection cannot be employed in this regard. Patients are too prone to take advantage of a guarded or qualified assent on the part of the physician, but they invariably throw upon him the responsibility for unfortunate results.

The medical profession should be better equipped for this prophylactic work by a more thorough knowledge

of venereology. The system of instruction as at present organized in most of our medical colleges is defective in this regard. In the presidential address before the American Dermatological Association, in 1890, I called attention to these defects and urged that the study of venereal diseases should be made an integral, necessary part of the course of medical education, and that a practical as well as a theoretical knowledge of these diseases should be made an indispensable requisite for graduation in medicine.

Physicians can do much in their professional capacity in instructing the young men of their *clientele* as to the dangers of licentious living. Too often the charge has been made against the profession that they recommend or sanction illicit indulgence as a means of health. On the contrary, the opinion of all medical men entitled to respect is that continence is not incompatible with health, and that harlotry is not a safe substitute for marriage.

This campaign of education should be extended to the high schools and colleges for young men. Unfortunately this has always been a forbidden topic. There is no reason why young men should not be forewarned of the pitfalls and dangers which beset their pathway—dangers into which they often ignorantly and unconsciously rush. Whatever may be thought of the innocuity of "sowing wild oats," its consequences are most often disastrous to the health of the individual. They should also be taught that self-restraint, personal purity, and respect for women are among the surest foundations of character. This education, it seems to me, should enlist the interest and cooperation of the moralist. For after all we must look to the education and training which will develop a higher order of morality in men as among the surest means of checking the evil.

Finally, the public should be educated to a recognition of the fact that the prostitute is largely the product of her environment. The vast majority of fallen women become so—not from choice or from innate depravity—but because of the hard and unjust social laws which force many of them into this life. Society should deal with them as unfortunates rather than criminals.

ON CERTAIN DISORDERS OF SLEEP.¹

By CHARLES A. DANA, A.M., M.D.,

of New York.

Professor of Nervous Diseases, Cornell University Medical College; Visiting Physician to Bellevue Hospital; Neurologist to the Montefiore Hospital; Corresponding Member of Société de Neurologie de Paris.

Nature of Sleep.—Whether or not the neuron moves or the neuroglia fibrils contract, this doctrine is true that sleep is the period during which the brain rests from its conscious activities, empties itself of the products accumulated by this activity and builds itself up for the work of awakening. There is much truth in the homology between sleep and the diastole of the heart, or the resting stage of a gland, and also in the suggestion that excessive sleep is like a flux, in which too much is carried away, while insomnia is a constipation in which morbid products are retained in the system.

Different Forms of Sleeplessness.—The most common dis-

order of sleep is insomnia, but this is only a very general term, for there are many kinds and degrees of sleeplessness. The approach of sleep may be accompanied with a strain and stress which are very uncomfortable; during sleep there may be an unnatural activity of the sensory and association centers causing dreams, or of the motor centers causing shocks, starts, and spasmodic symptoms. Ordinary control of the visceral centers may be lessened, causing discharges from the bladder, sexual organs and intestines; or the vagus may let go its hold and the patient be awakened by palpitations and dyspnea. The sensory centers may be stirred up causing the patient to awaken with sensations of light, colored scotomata, thundering noises, violent vertigo, or terrific pain. In fine, the ordinary smooth current of the subconscious activities breaks against some pathological condition, and now one symptom, now another is thrust out and so unpleasantly disturbs the sleep and awakens the sleeper.

It is to some of these phenomena that I wish to call your attention this evening.

The Fear of Insomnia.—I would like to say a word in the beginning about the seriousness of insomnia. It is sometimes a much overrated and overtreated symptom. Nervous people who cannot sleep well often get the idea that that they must sleep or they will get ill, possibly crazy. Hence, an artificial apprehension is created, and the patient becomes as solicitous about his 8 hours of sleep as the constipated hypochondriac is about the daily movement of his bowels. He makes his whole life and that of his family conform to the acquisition of nocturnal quiet. He restricts his evening meal, gives up all study, social life, and evening amusements, takes the back room, puts blankets over the doors, stops the clock, and poisons the back-yard cats, all to secure his eu-hypnosis.

As a matter of fact, adults can get along very fairly for a long time with from one-half to two-thirds the regular hours of sleep if they nightly rest in bed for 10 or 12 hours, and therefore, I hesitate before I treat insomnia in the sane, and never treat it with drugs, except temporarily, for there are no good drugs for the trouble.

Morning Insomnia.—Insomnia has all kinds of phases and, as is found by questioning those who suffer, it does not always mean the same thing. There is a very common type which is extremely annoying, and which has a rather distinct etiology and therapeutics. It is what I term "morning insomnia." In these cases the patients go to bed at the ordinary hour and go to sleep without any trouble, but wake up at 2 or 3 o'clock and then lie awake, or, at best, have only a little imperfect slumber for the rest of the night. Such cases occur most often in persons over the age of 45 or 50, and are associated with the development of degenerative changes in the arteries to which is the added factor of ill-health or worry. It may be an accentuation of a habit formed in youth, of very early rising. It is natural in old people to wake up early in the morning. When this symptom comes on, however, in middle or shortly after middle life, it is a very annoying and a morbid condition. Such patients often are helped by general tonic treatment, and by giving the heart tonics and arterial depressants, such as glonoin, potassium iodide, and strophanthus. They often also get some relief by getting up and taking a drink of hot milk or hot water, or some simple food. A small dose of bromide (10 gr.) or of trional (5 gr.) at bedtime helps them.

¹ Read at a meeting of the Bellevue Hospital Alumni Association, December, 1900.

A man of 61 came to me complaining of morning insomnia. He had a slight apex systolic bruit and signs of arterial sclerosis but no other organic disease. For the past 15 years he had had morning insomnia, and for 6 years had kept a daily record of the number of hours he slept. This averaged 5 hours and 20 minutes, and had not varied half an hour in any month, summer or winter, by the sea or in the mountains. The range was from 5 to 6 hours.

There is another form, however, of morning insomnia. When this occurs in younger people, generally in the thirties, the symptoms are, if anything, rather more marked and distressing. The patient goes to sleep satisfactorily, but wakes up at about 2 or 3 o'clock and lies awake in a state of nervousness and discomfort until the daylight comes.

Mr. L. A., 33 years of age, came to me with this type of insomnia. He was a man of good physique, and sound in all his organs, except that his heart was not a very strong one. He was of a nervous temperament; one sister was insane and one brother neurasthenic, but he, himself, was an intelligent, well-balanced man. His habits were good, he was careful of his diet, and as regards indulgences of all kinds. There was a slight rheumatic factor in his history and he had a rather irritable heart. He was treated by me for his morning insomnia with very little relief for considerable time. He did not respond to tonic measures, to anti-rheumatic measures or to the ordinary hypnotics. He would go to sleep at 11 and wake at 2 or 3 A.M., no matter what I gave him. I discovered, however, finally, that he was carrying a very heavy burden domestically and financially and that he had, although he did not confess it, feelings of depression nearly all the time and that a fixed idea of a worrying character was with him. When circumstances changed so that this disappeared he promptly got over his insomnia.

A very similar case under my care is that of a man, aged 30, whose bodily organs were sound except that he had a slight blowing murmur at the base of the heart over the aortic valve. He had been very well, until he found that his family and children were beginning to suffer. Although he ate well and looked well, his sleep became impaired. He would go to bed at 9, go to sleep in about an hour, wake up at 2 or 3 o'clock in the morning and stay awake all the morning thinking of his troubles.

In this, as in other similar cases, a fixed idea of a depressing character is working upon the brain all the time, and it is the important factor in finally waking the person up after he has gone to sleep, there being a sort of subconscious activity of the brain which finally bursts into consciousness and rouses the patient. No doubt the other awakening factors are defective heart and some neurasthenia entering into the cases; but happiness is the cure and is the best hypnotic in these cases.

Motor Shocks.—Sometimes persons go to sleep normally, but have their sleep disturbed by a succession of awakenings due to motor, sensory or psychical discharges. One very distinct form of intermittent awakening is by motor shocks.

Just as the patient is dropping asleep he suddenly wakes with a start. There is usually a very decided spasmodic extension of the legs and sometimes a jumping of the whole body. The patient is at once awake and the spasm is not repeated and he soon falls off to sleep again. The attack may occur several times before sleep is permanently secured. It is usually simply an evidence of fatigue and nervous irritability and rarely requires anything more than rest. In some instances, however, this condition continues through the night and becomes very annoying. It may even end in some serious condition.

A man of 35 had suffered from neurasthenic insomnia for 3 years and had got in the habit of taking trional in 20-grain doses at night. Under advice he stopped it, and for a long time was annoyed by these motor shocks. A return to trional stopped it and another attempt to break off the habit led to the same result.

I have a patient whose case shows that motor shocks may end seriously. She is a single woman; age, about 38, who for 10 years has suffered from neurasthenic troubles of a mild but persistent type. She suffered from general weakness so that she could not walk far or sit up long nor do any physical labor. She had rather frequently some slight amount of vertigo, she often had attacks of migraine, and slight exertion would bring on feelings of weakness and dizziness and pain in the head and back; when quiet, however, her symptoms were very few. She had always been accustomed to sleeping well and her appetite, digestion, and nutrition were good. She was of a nervous temperament and one brother had been a sleep-walker in early life. She herself had always been a very sound sleeper until the last two years of illness. Objectively she showed nothing but a rather weak heart with a functional murmur over the pulmonic valve. In the last two years she had had attacks of intermittent heart-beat which annoyed her a great deal. She had never had any fainting turns or any spasmodic troubles of any kind. The heart intermissions would occur during the daytime and in later periods annoyed her when beginning to go to sleep at night. About two years before her severest symptom developed, she suffered from startings just as she dropped off to sleep. These occurred only rarely, were not often repeated, and gave her but little annoyance. In the summer of 1900, however, both the sense of the intermission of the heart and the startings at night increased in frequency until finally when she went to bed she would be annoyed for 3 or 4 hours by repeated startings, it being 12, 1, or 2 o'clock before she finally got to sleep. She would have 20 or 30 successive starts during the night. All of this broke up her rest and disturbed her generally. On July 5 she retired as usual, but the startings continued through the night and until 5 o'clock in the morning. The skippings of the heart annoyed her occasionally also. At 5 A.M., just as daylight was breaking, she started up again and felt at the same time a cold sensation on her left side. She sat up suddenly in bed and felt a profound sense of objective vertigo. She called for her maid and then fell back and lost consciousness for about a minute. After this she felt dizzy and uncomfortable, but had no more starts until half-past 10 in the forenoon. She then had another severe one; sat up, got extremely dizzy and lost consciousness. At the same time she was found by the nurse in a state of slight, general clonic spasm. These spasms lasted only for a few seconds. She became conscious after a few moments. After coming out of this she was very dizzy again and vomited a good deal during the day. In the evening she had two more of these seizures. She was then seen by a physician who gave her bromide and she slept. She was seen by me next day and placed upon iodide of potassium and small doses of bromide of potassium, not larger, however, than she had had on previous occasions. She was kept upon this for several months and had no recurrence of the attacks in any way. For several weeks she passed very bilious passages.

The whole history of the case would suggest that out of a simple, persistent and predormital start there had developed some attacks of an epileptic character. Still, I am loath to believe that they were genuine epilepsy, for the patient had never had any signs of any type of petit mal before and inherited no tendency in that direction. They were more likely symptomatic of the weak and intermittent heart-action.

It seems to me that "motor shocks" are due to the change in the circulation of the brain that occurs while passing from the waking to the sleeping state. When this takes place in very irritable and tired-out brains, a slight motor explosion is brought about. In fact, the cardiac mechanism seems to be a very important one in the production of bizarre types of sleep disorder. The condition of the liver is also an important factor. One of the causes of the predormital starts is perhaps the removal of the inhibition exercised on the motor cortex by sensory stimuli from the outside world, especially from the visual organs. A girl of 12 who has frequent abortive attacks of epilepsy, has always

starts and slight seizures, when she goes suddenly into a dark room and even when she closes her eyes. She has to have a light in her bedroom at night and has had to give up closing her eyes when she says her prayers at church.

Psychical and Sensory Shocks.—At times persons are disturbed by sudden wakings from sleep accompanied with a sense of anxiety or distress over some particular idea; generally some work forgotten or duty neglected or apprehension which seems about to be realized. In these cases there is no sensory shock and no muscular starts or particular motor disturbance. The patient simply wakes suddenly and sits up in bed with a fear upon him that something should be done or ought to be done. Upon realizing the real state of affairs he falls to sleep and then, after a time, starts again with the same apprehensive idea.

A lady, 35 years of age, married, childless, of nervous temperament, had always been a good sleeper. She had had weak digestion and was rather neurasthenic. She underwent a severe strain in organizing certain charitable work involving much responsibility. While doing this, and for two years afterwards, she became subject to disturbances of sleep of the above character. After sleeping an hour or two she would suddenly become quite wide awake and sit up in bed with a sense of fear that she had left something undone about her work. After a moment she would realize the state of things and go to sleep again, to be again awakened; and this was repeated through the night. The sudden awakenings were not convulsive starts or associated with auras. They continued as a kind of nervous habit two years after she had been relieved of her responsibilities and when she had regained comparative health. They returned a year later when she had again become neurasthenic.

Sensory Shocks.—Dr. Weir Mitchell, in his book on nervous disorders, 1881, describes a condition somewhat analogous to this which I have described, but not identical with it. He refers to his cases as illustrations of sensory shock and finds them much more frequently in women than in men.

"When just falling asleep, one of his patients became conscious of something like an aura passing up from his feet. When it reached his head he felt what he described as an explosion. The sensation was that of a pistol shot, or as of a bursting of something, followed by a momentary sense of deadly fear. These sensory shocks may be accompanied by a flash of light or a sense of odor, or an abrupt and general motion, such as the ordinary attack of any violent and sudden sensation."

In the patient whose case I have described, there was nothing in the shape of an aura, nor in most of the cases which I know has there been anything like a sensory shock. These shocks, whether of psychical sensory or motor character, occur in neurasthenic and hysterical persons and are not associated with epilepsy.

Waking Vertigo.—A condition belonging to the class of sensory shocks may be termed "waking vertigo."

A man, 58 years of age, suffered from recurrent vertigo which he had had at various periods in the previous 15 years. His father had been very deaf, and he had a sister who suffered from Menière's disease. He himself had always been a healthy man with no specific history and no history of excesses of any kind, except that he had been a very hard worker. He had never had headaches, but had some inclination to sluggishness of the liver and suffered from bleeding piles. He was always a sound sleeper. In the earlier periods of the vertigo he used to be suddenly awakened up at night with an intense feeling of objective dizziness. This always occurred when he lay upon the right side. If, during

sleep, he turned over on this side for a time, he would suddenly be roused and sit up in bed with a feeling of dizziness and a sense of alarm in connection with it. This speedily disappeared, and if he turned over upon his left side he had no more trouble. The attacks were especially apt to occur when he suffered from what he termed "biliousness." At this time also he awakened with numb fingers and sometimes, sleep palsy. The attacks were, as he said, "very dreadful." They disappeared under tonic regimen and attention to the condition of the liver. When examined by me he presented no objective signs except a rather large heart and a systolic murmur at the apex, but he had no subjective symptoms of cardiac trouble and could ride a bicycle and go up stairs without any difficulty. Whether he had the heart trouble at the time of his previous attacks, or, at least, whether it was of any serious consequence, is very doubtful in my mind. The attacks must be ascribed to some mechanical cause. Theories as regards it could easily be developed, but I know of none that is perfectly satisfactory. That the position in some way interferes with the portal circulation and disturbs the hepatic function is perhaps the most likely explanation.

This waking vertigo is a condition not very rare in those who have chronic vertiginous troubles. Usually they suffer from an unpleasant dream of falling or of being carried swiftly along, an unpleasant sensation finally awakening them, and they sit up finding themselves in the midst of an attack of vertigo. It sometimes occurs as an awakening aura of epilepsy.

Migrainous Seizures in Sleep.—Migraine sometimes produces sensory shocks or perhaps less explosive disturbances that lead to sudden awakenings and broken sleep. The migraine occasionally takes a fulgurating type in which the patient, with hardly a moment's warning, is taken with a terrific pain in the head accompanied with nausea and eventually all the classical symptoms of the disease.

One of my patients, a man of 55, is often waked without warning from a sound sleep by a terrific temporal pain, which keeps him in agony for several hours, then gradually abates. This nocturnal attack of migraine is precisely similar to nocturnal spasms of epilepsy, and is measurably helped by antiepileptic remedies. The less sudden arousal of a patient with migrainous pains is quite common.

Waking Paresthesia.—A neurasthenic woman of 30, anemic, and overworked, was constantly awakened from sleep by her arms and legs going to sleep. The sensations would arouse her; she would wake, rub her limbs till they felt normal, and drop off to sleep again, and again be awakened. Sleep thus became imperfect and distressing. Two patients, reported by Schurster, would go to sleep quietly, but soon after would awake with a feeling that they had lost their muscle-sense and sense of position. The attacks came on successively during the night and allowed no sleep.

The condition here is similar to that of waking-palsy or waking-numbness,² only in the cases referred to, the sensations of numbness and anesthesia come first and are the cause of the awakening. They soon disappear but recur repeatedly, breaking up the sleep. Such attacks are more apt to occur toward morning, while the motor shocks occur often in the earlier part of the night. It is as though the motor cells lose their irritability more slowly and go to sleep later, while the sensory cells begin to become irritable sooner as the morning comes on. They precede the motor cells both in going to sleep and awakening.

² Waking-palsy and waking-numbness are very common symptoms and are generally and rightly considered in most cases to be due to a rheumatic or lithemic condition.

This is, in a measure, similar to the phenomena observed in diseases which cut off the peripheral nerves or injure the conductivity of the spinal cord, when sensory symptoms come on first and disappear first.

Painful Sleep.—(Hypnalgia, dysoneiria.) A chapter might be written upon the psychoses of the night; by which I mean those peculiar and unnatural mental states which come on as bedtime approaches and which mingle with or disturb the sleep. The period of retiring gets to be with some people who sleep ill, an event looked forward to with despondency and dread almost amounting to terror. On retiring they toss about, the mind jaded with worries and depressing emotions. They get up, walk about the room, read, take their medicine, go to bed again, still with no relief until perhaps toward morning, under the influence of some drug, they finally drop off. This is a state, of course, which is to a certain extent experienced by all sufferers from insomnia, but in some instances the condition during the night amounts to an acute melancholia, while in the daytime they are fairly comfortable.

Mr. J. H. R., a married man and traveling salesman, came to me some time ago with such a story. He had been well until about three years ago. He had always been a hard-working man, a moderate drinker and smoker. He showed no distinct objective symptoms, but gave the rather ordinary history of an irritable type of neurasthenia. His worst trouble was at night, during which time he suffered from disturbed sleep and a mental depression which was most excessive and to him alarming. He looked upon the approach of night with absolute horror. The condition I characterized by the term of "night despondency" because it was so sharply marked and acute.

The condition in which sleep is not refreshing or enjoyable, but actually a pain, has been called hypnalgia.

Dysoneiria.—Absolutely healthful and restful sleep is dreamless; and hard dreaming is largely a product of modern civilization; yet dreaming, like drinking, in moderation is harmless and not even disagreeable. This is the common experience and is confirmed by systematic observation. In an analysis of 118 consecutive dreams (Strong, *American Journal of Psychology*, October, 1900) there was an unpleasant emotional element in only 29 and here it was not acute. Painful dreams are usually incidents in early sleep and are often readily traced to indiscretions accounted sufficiently enjoyable to overbalance the nightmare. The sleep of early life is peculiarly sensitive to irritations from below the diaphragm. In later life it is more affected by the heart, bloodvessels and lungs. It is rare for an adult to be disturbed by disagreeable dreams.

There are, however, conditions in which sleep is a continuous succession of painful or disagreeable dreams. The moment sleep begins dreams begin, and when the patient awakens it is with a feeling that the whole night has been a series of fretting, depressing and annoyingly incoherent incidents.

A lady of 35 has had about seven attacks of epilepsy annually in the past six years; she has some chronic headaches but is otherwise well. She takes about 40 grains of bromide a day. She says that every night the moment she goes to sleep she begins to dream, and she keeps it up till morning when she wakes up tired and unrested; the dreams are unpleasant but not frightful. They make her sleep a burden.

A neurasthenic man of 30 years, sound of body, sensitive and inclined to despondency, tells the same story. He goes to sleep instantly, but begins at once to dream of trivial but unpleasant things, and wakens tired out. He agrees that the free play of fancies in dreaming is more wearying than systematic mental effort.

Such people are never quite well. They are usually tired out and have poisoned or degenerate brains.

The condition of unpleasant dream-slumber is called dysoneiria. It can be artificially and acutely induced by tobacco, coffee, and other poisons.

Waking Syncope.—It is a pretty safe general clinical rule to say that all serious spasmodic disturbances that occur in sleep are of an epileptic character. There are, however, a good many minor disturbances not of a convulsive character but associated with mental aberration or fainting turns which are often very puzzling and which belong, perhaps, sometimes to the epileptic class and very often may be considered simple evidences of a hysteria or neurasthenia, or of some temporary disturbance of the vascular mechanism.

A lady of 45, married, and the mother of several children, came to me in great distress of mind because it had been intimated to her by her nurse that she had nocturnal epilepsy. She was a woman of nervous temperament, but very intelligent and usually self-controlled; still, she was inclined to fits of depression and at times to hysterical outbreaks. As a girl she would often faint; once when vaccinated, again after taking a very large or powerful cathartic, again once when riding in a very hot car while pregnant with her first child. These attacks were simple fainting turns without any convulsions. When about 30, while nursing her baby, she would sometimes be awakened up suddenly at night by his cries; she would jump out of bed, run quickly to him and then faint away; she would remain unconscious for a short time, then get up and attend to her task. These nocturnal fainting turns ceased as the baby got older. Some 10 years later she became very much depressed and neurasthenic and took the rest-cure under my care for a period of several weeks. Twice during that time she awakened up suddenly at night and then went off into a fainting turn without any observed spasm, however. Four years later, while sleeping at night, her boy being in a neighboring room, called to her in a hurry. She jumped out of bed and had this same fainting turn. It seemed to me that I was not justified in calling these attacks epileptic, although I regarded them with some suspicion. The patient had a rather weak heart and was not a strong woman and it might easily be, it seems to me, that the sudden shock of being roused from sleep and getting up on the feet would cause a fainting turn, owing to the sudden change from a horizontal to a vertical position and the sudden demand upon the exercise of the mental faculties before the heart had time to adjust itself to the new situation.

Nocturnal Oratory.—Automatic disturbances of sleep such as sleep-walking and talking, are seen rarely and almost always in children. They are not of any serious significance, and rarely come to the attention of the neurologist.

Automatic phenomena occurring in the adult during sleep are of importance. They are not seen often in frankly developed epilepsy and yet they are usually significant of this.

A common form of this trouble is one called nocturnal oratory.

A man of 35 and lawyer by profession; a healthy, strong, vigorous man, came to me complaining that his wife did not like the way in which he passed the nights. He would go to bed and go to sleep like a normal individual, but in the early morning hours he would suddenly sit up in bed and say: "boo! boo! boo!" This would be followed by a short oratorical display upon some passing topic. For a short time he would quiet down and then go to sleep again. In the morning he would sometimes remember these attacks, but this was not always the case. At one time his wife, being a little irritated by his habit, tried to persuade him to stop, when he jumped at her and held her rather violently, quickly, however, quieting down and resuming his elocution.

I assumed the attacks were not associated with any

nightmares or dreams or any emotions of terror of any kind, nor could they be related to any habits of self-indulgence. I took them to be of an epileptic character and under the use of bromides they gradually ceased.

In the foregoing I have considered a special type of insomnia—morning insomnia.

Disturbing phenomena of sleep causing more or less insomnia, and these I classify as:

Motor shocks, psychical and sensory shocks, including waking in fright, waking sensory shocks of various kinds, and waking parasthesia.

Painful sleep, in which there is a kind of nocturnal melancholia, and in other instances a series of painful dreams (dysoniria).

Certain epileptoid and automatic disturbances of sleep.

A large part of the above phenomena occur from somewhat similar causes, viz., neurasthenia, lithemia, arterial sclerosis, and cardiac weakness, and a few can be attributed to digestive disturbances, and a few perhaps to abortive forms of epilepsy.

The treatment of these symptoms is the treatment of the underlying condition. They are usually easily helped by bromides and hypnotics, but these drugs are not often curative. It is especially dangerous to use the ordinary hypnotics; and I have come to the belief that all sleep-producing drugs are bad and useless in dealing with chronic and established neuroses. More can be accomplished by heart and general tonics, by dealing with the lithemia and arterial sclerosis and thus promoting the patient's general health. Exercise in moderation and long drives or long exposure to the fresh blowing air, are the best hypnotics given, also peace of mind, and especially a removal of that dread awakener—fear of not sleeping. The safest medicinal agent, if any is to be used, is single small doses of bromide, persistently kept up.

GENERAL METABOLISM IN DIABETES MELLITUS.*

By DAVID L. EDSALL, M.D.,

of Philadelphia.

Instructor in Clinical Medicine in the University of Pennsylvania, and Assistant Physician to the University Hospital; Associate of the William Pepper Laboratory of Clinical Medicine.

THE fact that my discussion is to be limited purely to metabolism in diabetes, without considering the relations of the metabolic disturbance to various organs, will necessitate omission of some points which are apparently of extreme importance in connection with the portion of the subject assigned to me. In the case of the pancreas in particular valuable discoveries have been recorded, and knowledge of these is practically essential to a proper conception of present views concerning the nature of the metabolic abnormalities in this disease. Such matters will, however, be more properly discussed by other speakers.

Since so large a number of points must be touched upon in discussing the general metabolism, I must repeatedly throw together facts which are rather distantly related in order to accomplish the duty which has been assigned to me within the limit of time.

The whole nutritional difficulty in diabetes, so far as is definitely known, is one that in an ordinary case relates, primarily, solely to the carbohydrates. The sum

total of the activity of the metabolic processes is practically normal; and the demand for and expenditure of energy are normal, except in so far as these are influenced by the disturbance of the carbohydrate "mechanism." Speaking freely, we may say that the diabetic expends the same amount of energy and suffers the same daily amount of tissue loss as a normal person, and requires in his food the same amount of energy and of material for repair as does the normal man. In one small way, to be sure, the diabetic does use, and therefore does demand, more energy than a normal man under the same circumstances. He goes through the labor of digesting carbohydrates, he produces carbohydrates within himself, and he, perhaps, constantly builds up glycogen and then produces glucose from it. All these processes serve a useful purpose in the normal subject and yield far more energy than they consume. In the diabetic, on the contrary, the energy of this labor is wasted, the partially prepared food is cast out without being used and without having furnished in return even the energy which it has itself demanded. Modifying the previous statement, therefore, in slight degree, a diabetic may, in regard to his nutritional demands, be looked upon as differing from the normal person only in that he uses slightly more energy in accomplishing the same amount of work. It is, however, essential to recognize that his real fault does not lie in a pathologically increased expenditure of energy and a consequently increased demand, such as is seen in many febrile and toxic states; it is a fault which does not lie in the demand for food or in the quantity of food ingested, but in a more or less complete loss of the normal ability to derive energy from carbohydrate food, and a consequent necessity for the vicarious assumption by the protein and fat of the role in producing energy normally taken by the carbohydrates.

It has always been known that diabetics hunger and emaciate; it has also long been known that a diabetic practically always excretes much more nitrogen than a normal man. The first impression that these facts give is that there is some essential factor in the disease which causes abnormal activity of tissue destruction, and that the excess in nitrogen excretion is direct evidence of excessively active protein metabolism. It was taught for many years by authorities that an essential feature of the disease was azoturia, and that the nitrogen excretion regularly exceeds the intake; and, indeed, the same statement is still often made or implied. As regards the fats, too, it may usually be observed that the loss in weight is more than the nitrogen loss will explain, and it is known that a diabetic early loses practically all his reserve store of carbohydrates. The conclusion is, therefore, justified that the man is losing fat, and his tissues themselves show this. Hence, wasting of the fatty tissues is often accepted as an essential part of the disease. In neither instance, however, is such a conclusion justified. The losses of fat and of nitrogenous tissues may be shown to be, in ordinary cases, purely secondary and due to the fact that the subject of the disease, though taking large amounts of food, is excreting so much of it practically unchanged that he is actually using for the production of energy an amount which is decidedly below the demand. The continuance of the demand for energy necessitates a proper supply, however, and the protein tissues and fat are broken down in order that they may yield this energy and not because their functions are abnormal.

* A part of a Symposium on Diabetes. Read at a meeting of the Philadelphia Pathological Society, January 24, 1901.

The unusual appetite exhibited by a diabetic is then a really normal appetite in that his tissues show no abnormal excitation of their food demands. Large amounts of food must be ingested merely because much of the food is wasted; and the subject emaciates only because he does not, as a rule, take a sufficient amount of the proper kind of food, that is, the kind that he can use; his supply of energy is below the demand, and his body protein and fat must fill the gap so far as possible. To appreciate the correctness of this view and the fact that the contrary teaching is erroneous, one must remember certain facts relating especially to the metabolism of the proteins in a healthy subject when the food supply is normal and when too little or too much food is given. There is not a sufficient general understanding of certain well-established facts which are all-important in this relation. In the first place, it should be more generally recognized that under normal circumstances the excretion of nitrogen is regulated almost entirely by the character and amount of food that a man takes and not by his manner of life as regards exercise, etc. If a mixed diet of normal quantity be given a man his tissues will in a very short time, usually a very few days, accustom themselves to the diet, and it may then be seen that whatever the amount of protein contained therein, his nitrogen excretion during a given period will be equivalent to the amount of nitrogenous food he absorbed during that period; in other words, that he maintains a nitrogen balance. It is necessary only to see that the total value of his food in units of energy is sufficient to meet the demand for energy, and that the daily ration does contain a certain amount of protein. The active tissues of the body are nitrogenous, and their activity means a certain amount of wear and tear, and consequently some protein is necessary to replace the loss. But this loss is small, and the protein may be reduced to as low as 30 to 50 grams a day without causing any loss of body protein during an extended experiment. Even active muscular exercise causes practically no increase in the nitrogen excretion if only the other foods are increased so that the total intake meets the increased demand; and a reduction of exercise, while the protein is still given in large amounts, does not cause any distinct reduction in the nitrogen excretion though it may cause the subject to grow fat. If food is given in very large amounts, more than necessary for the body needs, the subject will generally grow fat, but a nitrogen balance is again soon reached even if very large amounts of protein are given. If, however, the food is reduced in total quantity below the amount which is necessitated by the man's expenditure of energy, a loss of nitrogen will be seen almost at once if the excretion be compared with the intake. This loss will occur even though a relatively large amount of protein is taken. If the man be now given an amount of food which will bring the total food value up to the point demanded by his circumstances, he will reach a nitrogen balance again. The increase in foods need not be in protein, providing the protein has not been reduced below the relatively low limit of absolute demand, for it has been conclusively shown that protein loss can be easily controlled by giving more carbohydrate and, to a less complete and satisfactory extent, by giving fats.

There are a number of conclusions that can be drawn from these facts, which are of importance in connection with diabetes. In the first place, protein is evidently

not stored in the body. This conclusion is not wholly justified, as Krug's work seems to show that overfeeding with protein may, under favorable circumstances, cause some storage. His results, however, are justly questioned, and even if accepted they show extremely slight protein storage (producing only 5% of the increase in weight as compared with 95% due to increase in fat), and it is probable that the conditions producing such a storage could not be long maintained. Secondly, the protein both of the food and of the tissues is evidently readily broken down; with a general excess of foods or with an excess of any kind of food, even of protein, the protein is broken down at once, the fats and carbohydrates being stored; while if there be a demand for more food than is given the body-protein practically always suffers. And thirdly, and much more important in direct connection with the question under discussion, it is evident that a negative nitrogen balance, while it may mean excess in the activity of protein metabolism, may mean merely that the subject is taking too little food, all told. In health this is evidently the explanation, and in disease it is the first thing to be thought of. Fourthly, and quite as important in diabetes, it is evident that a nitrogen loss may, with healthy nitrogen metabolism, be converted into a nitrogen balance if more food is given, and that it matters little what form of food is given so long as the protein is not extremely low and the total value in energy units is normal under the circumstances. The possible explanations for the increased nitrogen elimination in diabetes are, therefore, three. It may be due to an increase in the ingestion, to a lack of sufficient food, or to a pathological essential increase in protein metabolism. The diabetic takes enormous quantities of food, hence the first factor evidently explains some of the increase in urinary nitrogen. It is not this alone, however, for the loss exceeds the intake. Of the other two, then, it may, in the ordinary uncomplicated case, be readily shown that a lack of proper food is at fault. A pathological increase of protein metabolism does sometimes occur in the late stages of diabetes, particularly when the patient is in danger of coma; but under ordinary circumstances, if the total caloric value of the food be calculated, and the loss in the sugar excreted be deducted, it will be found that the diabetic is making use of food only in amounts too small to meet the necessities of the occasion. If now his fats and proteins be increased to such a point that the total food value, after deducting the excreted sugar, is equal to or greater than the amount he needs, it will be found that the nitrogen balance is normal, and he may even retain nitrogen until the previous loss is replaced. Evidently, then, the protein metabolism is normal. As to the fat, conclusions are much more difficult to reach, except by inference. As has been stated, however, if a diabetic is given sufficient food, with consideration of the sugar loss, he will cease to lose weight, and with more food will gain weight, more even than the protein retention will explain. He tends, therefore, to retain fat and not to destroy it, if given the opportunity by being furnished enough total food, for a carbohydrate retention cannot explain the increase in weight. Further, there is no evidence of any increase in the oxidation of fats in studies of the respiratory quotient. There is also no good evidence that fats can contribute largely to the formation of carbohydrates in the body, indeed, the most satisfactory evidence points against this; there is, therefore, no opportunity for an indirect increase of fat de-

struction through contributing to the sugar production and loss. And finally, many cases of diabetes even show a distinct tendency to obesity. There is, therefore, no reason for believing that there is any increase in the oxidation of fats, either direct or indirect, excepting in an attempt to replace a deficit in the food.

But while there is no destruction of fats and protein in diabetes, excepting that which has the normal purpose of supplying the energy demanded, there is an evident disturbance of the metabolism of the carbohydrates, which is most easily seen in the characteristic and generally known symptom, glycosuria. The primary reason for this disturbance is both the most important and the most obscure question in diabetes, but valuable facts concerning the abnormality are known. Normally, we take the carbohydrates of our food chiefly in the form of hexoses, *i. e.*, their molecules contain six atoms of carbon, or a multiple of six. It is now known that our food does contain pentoses in considerable quantities, and that they play some part in our nutrition. It is not improbable that they are of decidedly greater importance in this way than is even now admitted, but they are probably largely transformed into hexoses after their absorption before they are used by the tissues. At present our interest certainly attaches chiefly to the hexoses. These are absorbed largely as glucose, though to some extent as levulose and also, in small amounts, as polysaccharids. Absorption takes place into the portal circulation almost exclusively. After this point the changes in the sugar are somewhat uncertain as to the main facts and entirely obscure in many details. It is quite possible that all the sugars, including glucose, pass through the glycogen stage before they are admitted to the general circulation. It is certain, at any rate, that practically speaking all the sugar normally admitted to the general circulation is in a form which gives the chemical and physical reactions of glucose, and that normally the amount in the general circulation is kept at a fairly constant but low level, the percentage being about 0.12 or 0.15. Any excess taken as food or formed in the organism is stored in the liver and muscles as glycogen, or if these reservoirs are filled to the limit, is changed into fat and deposited as such. If the supply is low the glycogen reservoirs are called upon and the glycogen is transformed into glucose and furnished to the circulation as such and not as glycogen. The existence of the glycogen reservoirs makes it possible to keep the percentage of sugar in the blood at the normal level in the long periods between meals, and in spite of temporary starvation or other unusual demands; the glycogen lost is soon replaced from a new supply of food, so that the total quantity of glycogen shows only temporary variations and a reserve is always on hand. The sugar admitted to the blood is, practically speaking, entirely used in the economy, the excretions containing only end products of its breakdown. The normal urine does contain a small amount of carbohydrate, and some of this seems to be glucose, but the quantity is too small to be considered of any practical importance.

The alterations in diabetes manifest themselves in all these main points—in the storage of glycogen, in the quantity of sugar in the blood, and in the striking change in excretion. The glycogen becomes reduced in amount and may almost disappear; sugar is found in the blood in abnormal amounts, constituting a so-called hyperglycemia, and more or less of this sugar is excreted in the urine as glucose, and the energy con-

tained in it is lost. The characteristic and distinguishing feature of diabetes is that these conditions are not dependent upon temporary causes, but are persistent and usually tend to increase. Any of the changes mentioned may occur temporarily as the result of numerous causes. The store of glycogen may be more or less completely reduced by starvation, particularly when associated with active muscular exercise; various nervous insults, particularly the *piqûre* of Claude Bernard, and many operative procedures will have a similar result, the latter probably acting largely through the nervous shock which they produce. Undoubtedly a hyperglycemia results in most of these instances, except in starvation, from the sudden flooding of the circulation with glucose formed from the glycogen, and hyperglycemia results in most if not in all of those conditions in which we observe so-called alimentary glycosuria. As to temporary glycosuria, this is a practically inevitable sequel of hyperglycemia when this reaches any notable degree, and consequently occurs in any of the conditions mentioned in which the percentage of sugar in the blood rises distinctly above the normal. It is in this way that the glycosuria may probably be explained when it occurs after trauma, experimental nervous insults, shocks in various diseases (as in gallstones), and in so-called alimentary glycosuria. In some cases a glycosuria is, however, independent of any mere sudden excessive production of glucose from glycogen or of a flooding of the blood with sugar by other means, such as the ingestion of large amounts of sugar. In some poisonings, particularly that produced by phloridzin, there is, without any hyperglycemia, a more or less decided glycosuria. In these instances the glycosuria is evidently not due to increase in the amount of sugar in the circulation, but to either a change in the chemical character of the sugar itself, or a change in the kidney permitting of the passage of the sugar. Infections also may cause glycosuria. They probably act as a rule through the production of a hyperglycemia, but may possibly act at times by alteration of the sugar or of the kidneys. But while it is possible that all the factors mentioned—poisonings, infections, shocks of various kinds, over- ingestion of carbohydrates (when protracted and particularly when largely of sugars), and even starvation,—may cause diabetes, and it is certain that some of these factors do at times produce the disease, the usual characteristic of the changes which they set up is that they are but temporary and disappear at once when the cause ceases to act, or at most soon afterward. If this is not the case the abnormality is actual diabetes. Of the conditions mentioned the one that most closely approaches diabetes is alimentary glycosuria, when this occurs persistently and after taking only moderate amounts of sugar. A normal person is evidently limited in his power of making immediate use of the carbohydrates which are absorbed from his gastrointestinal tract. Under normal circumstances the sugars absorbed are formed gradually during the process of digestion, and hence are absorbed in only small amounts within a given time. Only small amounts need to be dealt with, therefore, at one time. If, however, a normal person is given readily absorbable sugar in large amounts he absorbs large quantities within a brief period, particularly if his stomach and small intestine are practically empty when the sugar is taken. If the quantity given is large enough, any normal person will react by the excretion of some of the sugar in the urine. The

most evident reason for this, and the one generally accepted, is that he is unable to consume or store quickly such large amounts of sugar, his general circulation is flooded with sugar, and his kidneys excrete the excess. In other words, the normal ability to consume or store sugar quickly is limited. It may be observed in a large series of abnormal conditions that while there is no actual diabetes, an alimentary glycosuria may be produced much more readily than normally, *i. e.*, the ingestion of quantities of sugar that are normally fully used in the economy results in glycosuria. Among the prominent conditions in which this occurs may be mentioned neuroses (traumatic and other forms), organic nervous diseases, chronic or acute alcoholism, infectious diseases, pancreatic disease, and exophthalmic goiter. It is found in disease of the liver at times, but not in the large percentage of cases at one time thought. The essential point of distinction between a pure alimentary glycosuria and diabetic glycosuria is that the former occurs only after taking sugars and ceases when the excess is excreted, while the latter occurs after taking carbohydrates in any form, and often even when no carbohydrates are taken, it is more or less constantly present, even under normal conditions of life, and it is persistent and shows a strong tendency to increase. Alimentary glycosuria is present in diabetes, but does not necessarily mean diabetes. When the assimilative power is decidedly low, however, there is a dangerously close resemblance to diabetes in that in both conditions the normal power of making use of carbohydrates is reduced; but in pure alimentary glycosuria the alteration is quantitative only, while in diabetes it is both qualitative and quantitative. One striking difference between alimentary glycosuria and diabetes is that in the former the sugar excreted is practically always purely the kind ingested, while in diabetes the sugar found in the urine is, with very rare exceptions, glucose. But while the sugar excreted in diabetes is nearly always glucose, there is a distinct difference usually seen in the effects of the ingestion of different sugars. While all forms of sugars almost always increase the glycosuria, glucose is always badly tolerated and more or less completely eliminated, and the various polysaccharids are also but poorly borne. There is, as a rule, some power of using lactose, and levulose is frequently consumed to a very considerable extent, and may even cause an accumulation of glycogen, and the latter point is one of importance in attempting to make the course of diabetes clear. Besides the effect of the carbohydrates of the food, a striking effect may be seen from the food protein and the protein of the body. It is now certainly known that both these forms of protein furnish some carbohydrate normally, though whether it is a mere splitting off of a carbohydrate molecule already present in the protein, or the carbohydrate is formed by a more complex synthetic process after the partial breakdown of the protein molecule, is not known. Normally, this carbohydrate, like that already found as such, is completely used in the economy, but in diabetes it frequently increases the difficulty and is more or less completely excreted. But certainly the carbohydrate formed from protein is more readily assimilated than that taken as carbohydrate, as the exclusion of the preformed carbohydrates from the food will frequently cause the glycosuria to cease, and it is only in severe grades of the disease that the carbohydrate formed from protein is excreted in large percentage. Fats do not, from all satisfactory

work on the question, seem to increase the glycosuria, or indeed to form sugar at all. Bouchard and Desgrez have claimed recently that they may cause increase of the muscle glycogen, however, and this may possibly prove to be true.

The power of using preformed carbohydrate of any variety is rarely or perhaps never completely lost. Rumpf has recently claimed to have shown its absolute loss, and some other writers agree with him that this may occur, though no conclusive evidence of it has ever been offered. There are a number of cases on record, however, in which the loss was almost complete, and there seems no good reason that it should not occur at times. There is, however, never an entire loss of the ability to use carbohydrates in general, whether preformed or produced from protein. The possible variations are from the almost complete (or possibly complete) loss of the use of preformed carbohydrates, to a very slight and variable loss. In general there is a tendency for increase in the disability, and if carbohydrates are taken in any considerable amount this tendency is usually increased, often strikingly so. The most rational explanation of this is that the carbohydrate function, already weak, becomes overtaxed and still further reduced if excited to any degree. The abnormality also shows a decided tendency to more or less protracted fluctuations in degree, and may even spontaneously disappear for varying periods. Daily fluctuations are also seen in the sugar excretion, but these are probably due, as a rule, chiefly to the pauses between meals and consequent variations in the amount of sugar absorbed from the gastrointestinal tract.

Turning now from the characteristics of the metabolic disability to its effects—the chief immediate changes which can be determined are, as stated, an accumulation of sugar in the blood, a reduction of the glycogen in the liver, and to a lesser extent of that in the muscles, and a loss of sugar in the urine. The most striking clinical effects are largely secondary to those mentioned; they are chiefly hunger, emaciation, thirst and polyuria. The hunger and emaciation are, as previously stated, evidently due to food loss through the excretion of sugar in the urine. They are due to the fact that while the subject of diabetes takes a normal amount of what to a normal man is useful food, a very considerable portion of this is actually not food to the diabetic and cannot be used as such, and is excreted practically untouched. Hence he provides his tissues with an abnormally small amount of the substances which they can use as food. The hunger and emaciation are then their expression of a lack of sufficient food. An explanation of the thirst is usually simple enough. It is entirely or almost entirely dependent upon the polyuria; the loss of water, in the excessive excretion through the kidneys, makes the tissues poor in fluid, and the symptomatic expression of this is thirst. The polyuria is not quite so readily explained. It is certainly in chief part and in most cases explainable through the existence of a hyperglycemia. The kidneys are so constituted that they will not allow of the passage of sugar unless it be present in the blood in abnormal amounts. When it is present in abnormal amounts, however, the kidneys practically always make an attempt to excrete the excess. The sugar must pass the kidneys in solution, and for the solution of large amounts of sugar, large quantities of water are necessary, hence polyuria is an almost inevitable accompaniment of glycosuria.

The fact that the kidneys allow the sugar to pass

when it is present in the blood in excessive amounts is commonly spoken of as if it were an overtaking of the kidneys, and the glycosuria is apparently usually thought of as an unfortunate occurrence. It is, of course, generally recognized that the glycosuria is not of itself the cause of symptoms, but is the expression of some abnormality further back in metabolism; but it should be recognized also that instead of being a misfortune in itself, the excretion of sugar through the kidneys in hyperglycemia may be looked upon as a happy event; it must be largely an altruistic and purposeful act of the kidneys rather than the mere expression of a limit of power in retaining sugar. Hyperglycemia is an unfortunate condition in many ways, and were there no attempt on the part of the kidneys to reduce the excess of blood-sugar so far as possible, the results upon the tissues of the mere hyperglycemia itself would probably soon become grave in nearly all cases of diabetes. These results of hyperglycemia are among the most important of the secondary effects of the metabolic disturbance. They consist chiefly in a striking tendency to infection and necrosis of the tissues. It is generally known that the subjects of diabetes have a very marked tendency to pyemia, to tuberculosis in particular, to sepsis, to gangrene, and to many other infections. The gangrene can be explained to a considerable extent through the arteriosclerosis; but considering the strong tendency that diabetics show to other forms of infection, it is rash to follow the recent tendency of some surgeons and medical clinicians, and attribute the liability to gangrene almost exclusively to the arteriosclerosis that is often present. As to the tendency to tuberculosis, to pyogenic sepsis, and to many other infections, there is fairly general acceptance of the idea that these are largely due to the hyperglycemia. The existence of an excess of sugar in the blood and other body fluids makes this a much more favorable culture medium for bacteria, and it is perfectly reasonable to consider that the peculiar liability of diabetics to infection is largely due to this alteration of the body fluids. There are two other factors which must be considered, however. A diabetic is often an extremely ill-nourished person, and his very severe reduction of nutrition certainly favors infection, as infection is favored in other conditions of malnutrition. The third possible cause has recently been insisted upon by Teissier, who found that the presence of glycogen in culture tubes largely or completely hindered the growth of various forms of bacteria. He considers these observations added testimony of the correctness of the view previously expressed by Roger and Amato that the reduction of the glycogen of the liver so commonly seen in diabetes favors infection by reducing the bactericidal power of the liver. This is a somewhat theoretical explanation which may have considerable truth in it, but the actual knowledge of the role played by the liver in the prevention of infections is not yet sufficiently accurate to base ideas chiefly upon that, and it is certainly not yet sufficiently proved that the glycogen in the liver prevents bacterial growth and activity. The hyperglycemia is almost certainly the most important factor in favoring infection; one fact which seems to make this very definitely evident is that v. Mering and Minkowski in their original communication on experimental pancreatic diabetes strongly emphasized the tendency exhibited by the animals experimented upon to acquire infection almost at once. This infection usually took place locally through the wound made in

operating, and this seems much more like local infection due to a proper condition of the body tissues and fluids than a tendency to general infection through reduction of the bactericidal power of the liver; the tendency to infection was also so rapidly developed in these animals that the reduction in nutrition does not seem to have played a very important role. In closing this portion of the subject it may be mentioned that it is claimed that diabetes is demonstrable by certain methods which consist in observing the reaction of the blood to dyes, particularly to methylene blue. These reactions probably depend almost exclusively upon the existence of hyperglycemia. The tests which have been used in this connection are those of Bremer and Williamson. Bremer has two reactions: one of them consists in a peculiar behavior of diabetic urine to stains, the other in alterations in the staining reactions of diabetic blood. Williamson's test consists in a rapid decolorization of a weak alkaline methylene-blue solution when diabetic blood is added to it. Investigation of Bremer's reactions has shown, as might have been postulated without special study, that while it is almost always present in diabetes when hyperglycemia and glycosuria are marked, there are other conditions of the blood and urine that may give an apparent reaction, and there are also so many possibilities of error in the technic of the preparation of the blood that the reaction is of no serious consequence in actual diagnosis. As to Williamson's test, it is, in the first place, necessary to carry out the reaction with the utmost care as to details, and errors in technic are very likely to occur. Furthermore, the only instances in which the reaction is likely to be of any real value are in cases in which there is no opportunity to determine the existence of glycosuria, for glycosuria, if present, is a sign which is much more readily and certainly demonstrated. Such conditions are probably at most two. One of them is the absence of glycosuria, while hyperglycemia is present. If such a condition exists it is extremely rare, and even if the possibility of its occurrence be admitted, certainly hyperglycemia can be present in only extremely slight degree without a coexistent glycosuria, and it is questionable whether a very slight degree of hyperglycemia could be determined by this rough test; probably it could not. The condition in which Williamson thinks the test is more likely to give useful results is in diabetic coma, when urine cannot be obtained for examination, and when one desires immediate security in his diagnosis. A negative result, however, under such conditions, could never be depended upon as indicating the absence of diabetes, as it is well known that preceding or during coma, glycosuria and hyperglycemia not very infrequently disappear more or less completely. For this reason alone it is probable that Williamson's test would be negative in a certain proportion of cases of diabetic coma, if glycosuria were absent. There are instances in which the bladder contains no urine, and yet glycosuria and hyperglycemia are present. In these extremely rare cases Williamson's test might be of value. It must be remembered, however, that up to the present the test has not been well studied in relation to the other conditions which might possibly give a reaction. From some investigations that have been made it appears that the reaction, or something practically undistinguishable from the reaction, may occasionally appear in other conditions. It would seem, therefore, that the possibilities of a negative result in actual diabetes and of a positive result in other con-

ditions make the test so far unreliable that it is a very insecure basis of diagnosis. The proper observation of the symptoms, together with the investigation of the urine, if this is possible, and the discovery in it of large amounts of acetone, diacetic acid, and, perhaps of β -oxybutyric acid, afford much more satisfactory and far more reliable methods of diagnosing diabetic coma.

The discussion of metabolism in diabetes would, of course, be incomplete without a mention of the conditions in coma; but the questions arising in connection with this complication are so intricate and have given rise to such extensive discussion that only the most notable points and those which seem fairly well established can be given. So far as nitrogen metabolism has been studied, it seems, while somewhat variable, to be very likely to suffer an abnormal excitation with the approach of coma. The subject of the disease, while previously in nitrogen equilibrium if properly fed, shows with approaching coma a loss of nitrogen which cannot be replaced by increasing the protein food within safe limits. The cause of this increase in metabolism is not clearly evident, though it is certainly an expression of toxemia. With the nitrogen loss the patient commonly suffers a loss of fat. The carbohydrate disturbance usually continues, and at the period when coma is approaching, has generally become of severe degree. One striking point, however, which is always worthy of being remembered, is that, as previously noted, in some cases the sugar excretion disappears as coma approaches and during the course of coma. This is perhaps due chiefly to reduction in the amount of food taken, and a consequent reduction in the amount of carbohydrates supplied to the circulation, though this is by no means a complete and satisfactory explanation. But the most notable facts about diabetic coma, so far as one is directly concerned with questions of metabolism, are the evidences of intoxication that precede or accompany the coma. The facts best known to the clinician are that acetone and diacetic acid are found in the urine in more or less considerable amounts. It has also been shown chemically, and is evident upon mere observation, that acetone is given off in large quantities from the lungs. Acetone is known to be toxic, and it was long taught, and is still widely believed, that diabetic coma is actually an intoxication with acetone. It has, however, been shown satisfactorily that acetone, while it may and probably does play some part in the production of coma, is far from being the sole or even the chief cause of the coma. Acetone is really an end product of the acids which cause the coma rather than itself the cause; and although acetone may readily be conceived of as contributing to the production of intoxication, it cannot be considered to be chiefly active in causing the peculiar symptoms seen in diabetic coma. In the first place, acetone is but mildly poisonous, and when given to man or animals, even in the amounts excreted during the course of diabetic coma, produces only mild symptoms, if indeed it causes any; also, the amount excreted shows no regular parallelism with the progress of the intoxication; and further, the symptoms produced by poisonous doses are not those of diabetic coma. It may properly be said, also, that it has never been quite conclusively proved that acetone is ever found in large amounts in the body, and a number of observers contend that all the acetone found in the urine is excreted as diacetic acid, and this is subsequently oxidized to acetone. This

view is probably not correct; the reasons given are sufficient, however, to show that acetone can not be considered to be the cause of the peculiar coma. But a still better reason is found in the fact that other substances are present in diabetic coma and preceding its onset, which show a close and almost constant relation to the symptoms, and which may, from analogy with the results of experiments, be fairly considered to be the cause of the coma. It is now well known that preceding and during coma there is so large a production of acids as to flood the blood and tissues with these, to reduce greatly the alkalinity of the blood, and to cause the excretion of large amounts of alkalies combined with the excess of acid. It is also well known to experimenters that administering large amounts of acids of various kinds will result in the appearance of a condition which resembles diabetic coma in several of its most distinctive features. Somewhat similar symptoms of intoxication may also be produced by giving to animals large quantities of those forms of food which will produce acids in large amount in the process of the breakdown of the food, providing that the animals are not accustomed to such a method of feeding.

The most satisfactory explanation of typical coma then, so far as our present knowledge goes, is to consider it a form of intense acid intoxication, due not to any special toxic agent, in its typical form, but to the mere excess of acid, and to the consequent reduction of the alkalies of the blood and tissues through their neutralization by the acid. The substance which is undoubtedly chiefly active in the production of the intoxication is β -oxybutyric acid. This has been shown, since the work of Minkowski and Külz first demonstrated that it may be found in this condition, to be present in large quantities during coma or preceding its onset in the great majority of cases. It has not any severe toxic action which is peculiar to itself; it is, however, present in such large quantities as to be capable of producing acid intoxication through its action simply as an acid. Diacetic acid is also found in large amounts when coma is imminent or present; it is very probably derived from the β -oxybutyric acid, though it is possibly separately produced. It is almost devoid of any special toxic properties and is active in the production of diabetic coma only through its acid properties, but it is almost certainly present in sufficient amounts in many cases to aid, at least, in the production of the acid intoxication; it is impossible to state this absolutely, since the amount of diacetic acid cannot be satisfactorily determined quantitatively. β -oxybutyric acid is, however, present in much larger amounts and is of itself somewhat toxic; it is certainly much the more prominent factor in the production of the coma. Acetone is a derivative of β -oxybutyric acid and diacetic acid, and is therefore chiefly the expression of the conditions causing the coma rather than itself the cause, though as previously stated its toxicity is sufficient to make it probable that it aids in the production of intoxication though not directly in the production of the peculiar symptoms of diabetic coma. There has recently been an attempt to demonstrate the possibility that diabetic coma is due to a substance which, besides its mere acid influence, has a special toxic effect, and which through this latter action produces the special symptoms of diabetic coma. Sternberg, assuming that β -amidobutyric acid might be present in diabetic coma, has investigated the effect of this acid upon animals, and claims to have produced

with it a condition practically identical with the peculiar coma of diabetes, and Grube states that he has confirmed Sternberg's results. Magnus-Levy very properly objects to the acceptance of these results, however, upon the ground that the amido-acids found in the human organism are of the alpha, not the beta, series, and that the theoretical assumption of the existence of β -amidobutyric acid is unjustified. There is also question whether the conditions produced were really those seen in diabetic coma. While it may be true that some special toxic agent produces the peculiar symptoms, this does not from our present knowledge seem at all essential. The conditions in true diabetic coma vary to a certain degree, and other acids beside β -oxybutyric and diacetic acids (lactic, volatile fatty acids, etc.) have been demonstrated to be present in large amounts in some instances, and were very possibly the cause of the coma in these cases; hence coma seems to be produced by a flooding with acids of various kinds. Also a condition practically indistinguishable from diabetic coma has been observed in a number of other diseases, such as carcinoma and pernicious anemia, when there was evidence of profound acid intoxication. These facts, together with the observation of experimenters that various kinds of acids produce a similar condition when the amount given is large enough, demonstrate with a considerable degree of certainty that the coma is at least in chief part due to the action of the acids as such, and not to any special toxic substance.

The source of the acids has been a matter of great controversy. It is demonstrated by both experimental work and by clinical observation that the use of carbohydrate food not only does not produce these acids, but tends to decrease any existing acid intoxication. It has until recently been very generally accepted that the acid intoxication is produced by destruction of proteins. It is well known that the destruction of proteins does produce considerable quantities of acid, and, further, one of the most striking reasons for accepting this source of the intoxication is that when acid intoxication occurs the subject is usually losing large quantities of nitrogen in spite of the large intake, and is therefore breaking down large quantities of the protein of the body tissues as well as of the food. It has, however, not been satisfactorily established that β -oxybutyric acid, diacetic acid, or acetone can be produced from protein, though the recent work of Blumenthal and Neuberg makes it seem probable that this may actually be accomplished in the human organism as well as artificially. Their work, however, is not yet confirmed. In the absence of thorough proof of production of these substances from protein, and in the very satisfactory demonstration, by Geelmuyden and Magnus-Levy in particular, that they may be produced from fats, the belief has become quite generally accepted that the fats of the food or the body, or both, are probably the source of the acids producing the intoxication. One must at present therefore consider the source of these acids to be chiefly the fats; though it is highly probable that the protein also contributes to their production, and it must be accepted as practically certain that proteins at any rate contribute to the acid intoxication through the production of other acids, since the breaking down of protein food always produces a considerable amount of acid. It has been very definitely demonstrated by both clinical observation and experiment that the acid intoxication occurring in diabetes may be due to the use of a protein-fat diet, or to break-

down of similar body tissues. A complete or almost complete restriction of carbohydrates from the food is very likely to be followed by the appearance of acetone and diacetic acid in the urine in diabetes, as is well known to clinicians, and the experiments of Gerhardt and Schlesinger show that a similar result may be produced in normal persons; while the substitution of carbohydrates for some of the protein and fat frequently causes the disappearance of the acetone and the diacetic and oxybutyric acids and the symptoms of approaching coma if they were present. In what way the carbohydrates exert this action is not fully understood, as such an effect may sometimes be seen when comparatively little carbohydrate is given. It seems probable that the carbohydrates in some way influence the metabolism of the protein and fat, besides reducing the quantity of the latter which it is necessary to give. While the appearance of large quantities of acetone, and more particularly of diacetic acid, in the urine furnishes what must continue to be the best general clinical index of the danger of the onset of coma, a more exact method of determining the degree of acid intoxication and its progress is by estimating the ammonia of the urine; one may practically always see that with increasing acid intoxication the ammonia excretion in the urine coincidentally increases and in most cases this increase is practically proportionate to the degree of intoxication with acids. The reason for this is that the acids produced in the body are normally neutralized largely by the fixed alkalies, only small amounts of ammonia being excreted. If, however, the amount of acid to be neutralized becomes much larger than the normal, the fixed alkalies do not suffice to neutralize the acids or they cannot be so largely used without causing a dangerous reduction in the alkalinity of the body fluids. Under such circumstances, according to the teaching of the Schmiedeberg school, which is the most satisfactory, the ammonia formed in the body, instead of being excreted as urea, unites so far as necessary with the acids and is excreted in combination with them.

An interesting fact which has been well shown recently by Gerhardt and Schlesinger, and has previously been indicated by the work of others, is that the excretion of calcium and magnesium, particularly of the former, is increased during acid intoxication, and there may even be a decided calcium loss which may be controlled to a considerable extent by modifying the diet or by giving alkalies. This fact is of great abstract interest, and it is wholly probable that it may have a good deal of actual clinical importance. The calcium salts play an extremely important role in organic chemistry in numerous ways, one of the most important of which in animal physiology is their influence upon coagulation of the blood. An influence similar to that just mentioned is exerted by calcium salts upon the action of other ferments than the fibrin ferment, and it seems not at all impossible that reduction of the calcium salts in acid intoxication may have an important relation to the symptoms produced during such intoxication. The results of metabolic experiments make it wholly worth while to investigate more thoroughly the effects of calcium upon the disease, particularly when there are evidences of acid intoxication.

In conclusion, the main theories concerning the definite nature of the disturbance in metabolism which produces diabetes may be mentioned. These are

that the disease is due to overproduction of sugar; that it is due to imperfect oxidation of sugar and its consequent accumulation; that it is due to insufficiency in the production of glycogen so that the sugars absorbed from the digestive tract or formed in the body constantly reach the circulation at once, and the excess, instead of being stored, is constantly being excreted; and that some special toxic agent is the primary cause. The first and last theories at present deserve little consideration. There has never been any proof offered that there is an overproduction of sugar; indeed, the testimony is wholly against such a belief. The whole amount of sugar excreted is never continuously greater than the amount absorbed, plus the amount that we know can be produced from the food-protein and body-protein which are being destroyed at the time. The theory of a special diabetic toxemia, which has recently been put forth by Leo, is based upon inconclusive experiments, which amount to nothing more than the production of glycosuria in a small number of dogs by injecting the urine of diabetic subjects. Urine from other diabetics did not give the same results, and there was no demonstration that actual diabetes occurred in the animals, or that a special toxic agent caused the glycosuria. The choice lies between the other theories—the disease seems to be either a loss of the normal power of destroying sugars, or a lack of the normal power of producing glycogen, and of controlling thereby the amount of sugar supplied to the blood. Either of these theories would satisfactorily explain the facts observed in most instances. The general tendency, more particularly of the v. Noorden school, is to put faith in the theory of imperfect oxidation of the sugars. The most important point upon which such a belief is based is that the respiratory quotient (the amount of oxygen taken in in respiration divided by the amount of CO_2 given off) is low in diabetes. Under normal circumstances the oxidation of carbohydrates in large amounts increases this quotient, while when the amount of fats being oxidized is relatively high, the quotient decreases. It would seem, therefore, that in diabetes the amount of oxidation of carbohydrates is below the normal.

This is serious testimony, but it is based upon a very small number of observations, and hence the influence of chance factors cannot well be excluded; and against such results may be adduced the fact that oxidative processes in general are certainly not reduced in diabetes, as it has been shown that many substances which are difficult of oxidation may be oxidized in large amounts by the organism of the diabetic. Further, under ordinary circumstances levulose and glucose are oxidized with about the same facility, but in diabetes levulose is assimilated but glucose is not. This points against suboxidation as the cause. Chauveau and Kauffman also found that comparing the venous and arterial bloods of the diabetic with those of the normal subject there was evidence of oxidation of the sugars in the diabetic subject as well as in the normal one. Their methods were subject to question, however. The work that has been done on glycolysis has not demonstrated anything clearly, unless it be, as Biernacki has recently claimed, that glycolysis is very variable in diabetes; Lepine's attempts, and those of others, to demonstrate the absence of the glycolytic ferment or reduction in its activity have not been successful, and his suggestion of a loss of glycolytic action of the body fluids in diabetes is therefore not at all supported by experi-

mental work. The theory of imperfect glycogen production is suggested by a number of facts, the most important of which is perhaps the observation that levulose is frequently made use of in large amounts by the diabetic organism when glucose is largely or completely excreted unused; and more particularly that levulose will frequently produce an accumulation of glycogen in the liver while glucose will not. This would seem to indicate that it is impossible in diabetes to produce glycogen from glucose, while this occurs normally with levulose. It seems improbable when viewed in this connection that the oxidation of glucose is at fault, because the levulose after producing glycogen in the liver is normally furnished to the circulation in the form of glucose; in spite of this it is largely or completely oxidized thereafter, apparently even by the diabetic in many instances. Further testimony of the possible correctness of this view has been recently furnished by the results of Sachs who found that extirpation of the liver in frogs did not alter the power of these animals to assimilate glucose, but did produce a strong tendency to alimentary levulosuria. He uses these results as testimony of the lack of importance of the liver in the production of diabetes; but since, as has been repeatedly stated, levulose is often satisfactorily assimilated by the diabetic while glucose is not, and since extirpation of the liver produces exactly the contrary conditions to those seen in diabetes, these results would seem to indicate also that if levulose passes the stage of glycogen production in the liver, it is properly used by the organism, and that the reason that levulose is well assimilated in diabetes is that there is still power of transforming it to glycogen while glucose cannot be so transformed.

A PRELIMINARY COMMUNICATION OF A STUDY OF THE BRAINS OF TWO DISTINGUISHED PHYSICIANS, FATHER AND SON.*

By EDWARD ANTHONY SPITZKA,

of New York City.

Surgeon in Medicine, College of Physicians and Surgeons.

To a great extent, the more recent studies of human brain anatomy may be termed one-sided, inasmuch as the numerous examinations made of individual cerebra were of such derived from criminals, lunatics, and other defectives, nay, most frequently from subjects whose life-history and characteristics were and remained unknown, or were unworthy of record. On the other hand, the brains of public men of professional or scientific eminence, whose actions and attainments were "writ large upon the pages of history" are seldom obtainable. In the words of Wilder, this is "both illogical and unprofitable." . . . "It is at once a reproach and an irreparable loss to science that the community has not yet been convinced that the preservation and study of one's brain is an honor to be coveted. Who can set a limit to the result that might have been attained from the examination of the brains of soldiers like Grant, Sherman, and Sheridan; of preachers like Beecher, Brooks, and Howard Crosby; of naturalists like Agassiz, Gray, and Jeffries Wyman; of lawyers like Tilden, Conkling, and Benjamin Butler. How long must sci-

* Read before the Association of Anatomists at Baltimore, September, 1900, and before the Section on Anatomy at the New York Academy of Sciences, February 15, 1901. In view of a preliminary study by the publication of which is contemplated the writer regrets that a number of those details essential to the latter and whose reproduction were unnecessarily repetitious.

ence wait for a general sentiment such as is embodied in the declaration of an eminent historian, that science is as welcome to his brain as his old hat, and that he wishes he had ten of them."

To this day only a few brains of eminent men have been studied and described: that of Chauncey Wright, a philosophical writer; that of George Grote, the well-known historian of Greece, and those of five or six members of the French "Société Mutuelle d'Autopsie." I might add that of a woman, Laura Bridgman, who, though bereft of the powers of language, sight, and hearing, displayed an intelligence and education of a remarkable degree. Less detailed descriptions were made of the brains of the mathematician Gauss, Dr. Fuchs and a few others.

In this view of the subject the writer ventures to assume that the presentation of the following preliminary account may not be uninteresting when it is learned that it is based on the examination of the brains of two eminent physicians, which have been "saved for scientific uses rather than wasted upon worms." But what is of especial importance and without precedent is that one is the descendant of the other, and furthermore, that their ancestors and several relatives of the same name had been for several generations physicians, chemists, engineers, and architects, and that the ancestral history is marked by many meritorious achievements. The brains of which I speak are those of Dr. Edouard Seguin, and his son, Prof. Edward C. Seguin, both of whom were distinguished for high scholarship and brilliant attainments.

BRIEF BIOGRAPHICAL SKETCHES.

The elder Seguin was born at Clamecy, Department of Nièvre, in France, on January 20, 1812. As I alluded

Dr. Edouard Seguin.

to above, his ancestors for several generations were eminent as physicians, architects, etc., ranking at the head of their professions in the department. Dr. Edouard Seguin received a very thorough education at the

college of Auxerre, and at that of St. Louis, in Paris. He then commenced the study of medicine with the celebrated Itard as preceptor, and was subsequently associated with Esquirol, the distinguished alienist and

Dr. Edward Constant Seguin.

psychologist, in his investigations. The study of what is now known as arrested mental development began with Seguin's devotion of his young life and talents to the welfare of the idiot children at the Hospice de Bicêtre, and for over 40 years he remained devoted to the cause he had made his own. The works he published have been recognized as authorities to the present time. In this country he was the pioneer in advocating the introduction of the metric system, and he is equally noted for his contributions to the subject of medical thermometry. His son, Dr. Edward C. Seguin, departed this life so recently that it and his work are yet a fresh reminiscence. With the favoring ancestry already alluded to, it is not surprising that the younger Seguin should attain his prominent position. Born in 1843 in Paris, and coming to the United States with his father in 1850, he received a public and high-school education in Cleveland, Ohio. In 1861 he began the study of medicine with his father and after a 3 years' course at the New York College of Physicians and Surgeons—showing his brilliant qualities even as a student—he graduated in 1864, being then only 21 years of age, and after having at that early age served as a medical cadet in the regular army. Among other appointments which he received, was that of house-physician at the New York Hospital. He developed a pulmonary trouble which was recovered from during a sojourn at Forts Craig and Selden, in New Mexico. From 1871 to 1885 he was lecturer at the College of Physicians and Surgeons on diseases of the nervous system and insanity. In 1873 he founded the clinic for nervous diseases in that college. He was a member of many societies in both hemispheres, and his contributions to the pathology and therapeutics of nervous disorders are especially

valuable and rendered his position in the literature of the medical world a very prominent one. He will always be distinguished as one of the pioneers of American neurology. An indefatigable worker, his labors were all characterized by a methodicity which has become traditional among his friends and pupils. He died on February 19, 1898.

BRAIN OF DR. EDOUARD SEGUIN.

The elder Seguin's brain was removed within 24 hours after death by Dr. E. C. Spitzka, assisted by Dr. R. W. Amidon, on October 29, 1880. Its appearance and texture were normal, but there appeared to be a trifle less cerebrospinal fluid than usual. The brain-weight was recorded as 2 pounds, 12 ounces, $5\frac{1}{2}$ drams, equivalent to 44.344 ounces or 1,257 grams. At the present time, after over 20 years' immersion in alcohol, this weight is reduced to 880 grams, the loss amounting to 377 grams, or 30% of the original weight.

The weights of the different parts of the brain* on December 3, 1900, were as follows:

Left hemisphere	365 grams.
Right hemisphere	367 grams.
Cerebellum	84 "
Isthmus	64 "
Total,	880 grams.

According to Marshall's tables the average brain-weight for a man of the height of 65 inches or under, and between the ages of 40 and 70, is 45.74 ounces (= 1,296 grams). It must not be forgotten, however, that the brain-weights of the French are somewhat less than those of the English which Marshall's figures represent; and if we remember that Dr. Edouard Seguin was about 64 inches in height and was in poor health for some time prior to his decease, his brain-weight of 1,257 grams cannot be said to deviate much from the normal figures, and, if anything, would point to the occurrence of some wasting of the brain-tissue from disease, or age, or both. Various estimates of Dr. Seguin's body-weight range between 125 and 145 pounds, giving ratios, as compared with the brain-weight, ranging between 1:45 and 1:52. The latter ratio was also found in the case of George Grote by Marshall, and was probably due to the same or similar causes.

In the following list of brain-weights of eminent men compiled by the writer from various sources, Dr. Edouard Seguin's position is rather a low one, but the idea that intellectuality always presupposes a heavy brain has long ago been demonstrated as groundless. Still, such a table has its value in showing that the maximum frequency of brain-weights of eminent men occupies a distinctly superior position as compared with those of ordinary individuals, and that the significance of brain-weight as an index of intellectual capacity must depend upon the proper collation of a sufficiently large number of cases, and the correlation of contributory and complicating factors.

BRAIN-WEIGHTS OF EMINENT MEN.

[This table is only provisionally arranged, as a few of the figures have not yet been verified by the writer. The

* The division of the cerebral segments was not made strictly in accordance with Meynert's plan, but according to a modification which utilizes the caudal border of the optic tract, and the tentorium thalami (riparia) as guides for a single simple incision; those of either side converge forward to meet in front of the chiasm; the usual cut through the callosum and lamina terminalis complete a trisection which leaves the prosencephalon and brain-axis separated as nearly the ideal as can be.

authorities for these weights have been omitted here, but will be fully supplied in the final report.]

Concerning the general form of the cerebrum the reader is reminded that during its immersion in alcohol for a score of years there has naturally been considerable shrinkage and flattening. Giving due allowance to this unavoidable distortion, its striking features can be enumerated as follows:

Marked development, with great breadth and fullness of the frontal lobes.

A great width and ample development of the parietal and temporal lobes.

Relative smallness of the cuneus in both halves, especially the left.

General tortuosity of the fissures and gyres.

A full and ample development of the left insula, especially of its cephalic (anterior) portion, the insular pole being very fully developed, and far better than on the right side. A portion of the left preinsula is visible.

The sylvian cleft is more horizontally directed than in most brains. This approach to the horizontal is more marked on the left side, and is generally considered an important indication of superior development.

* The weight of these brains when fresh will always remain unknown.

The left parietal and paroccipital fissures are separated while on the right side they are confluent. This arrangement is quite rare, having been found in 6% of cases by Wilder¹ and the writer.²

The fissures on the whole are characterized by their generally tortuous paths, by their great depth, and perhaps by a greater frequency in their deep interruptions by vadums and interdigitating subgyres. In general the gyres are neither of maximum nor minimum width; their size seeming to be determined by a tendency to crowd the greatest number—more or less regularly and evenly—into the available space. They are bold and massive, so that in spite of the intricate fissuration the configurations of the brain are neither “overcrowded” nor “cramped-looking.” There is that in the “physiognomy” of the brain as in the son’s, which it is impossible to describe, otherwise than in terms the very use of which would suggest the having preconceived notions of a relation between structure and function, to say that it portrays the culture, refinement and intellectual capacity of its erstwhile owner when living.

The indices of the lobes* of the left hemisphere are :

Frontal index	60.4
Parietal index	22.2
Occipital index	17.4

On the right hemisphere :

Frontal index	58
Parietal index	20.6
Occipital index	21.4

These figures indicate in a measure the better development of the left frontal and parietal lobes.

The frontal gyres are the most complex of the entire brain, being particularly rich in their windings, though the parietal gyres are almost as rich in their development. The subfrontal gyrus (Broca’s convolution) of

Fig. 1.—Frontal portion of the left hemisphere of Edouard Seguin (father) showing exposed area of the preinsula, and also the well-developed opercula.

the left half is very well developed, as might be expected, in a right-handed individual with a left speech center. (See Fig. 1.)

* These indices are measured along the dorsomesal border of the hemisphere, from pole to pole, and are expressed in terms regarding the entire length so measured as equivalent to 100.

Upon the left half the “intraparietal fissural complex” is remarkable in that all four of the so-called segments are distinctly separated from each other, a condition rarely observed and found by Cunningham³ in only four hemispheres out of sixty-two; once on the left, once on the right, and once on both halves.

Fig. 2.—Occipital portion of left hemisphere of Edouard Seguin (father) showing the remarkably distinct exoccipital fissure (EOP) as well as the paroccipital isthmus, marked by the cross (X). Oc marks the occipital fissure. Photograph by Dr. E. Leaming.

Mickle⁴ regards such bridging of the so called “intraparietal sulcus” as a mark of superiority in brain evolution. The paroccipital fissure, which is of the true zygal type, is absolutely separated from the parietal fissure by a well-developed “paroccipital isthmus.” (See Figs. 2 and 3.) Upon the right half there is a confluence of the corresponding fissures. This brain, therefore, presents an additional example of a rare arrangement hitherto unnoticed in the brains of moral and educated persons, at least so far as the writer knows. Of the six cases recorded by Wilder¹ there were three of unknown history, while the remaining three whose history was known, were insane, one a Swiss woman, one an engineer, and one a negro. The writer² has since found a similar arrangement in six of the one hundred brains of dissecting-room subjects, derived mainly from the pauper class dying in the municipal hospitals and charitable institutions.

As stated above, the occipital index on the left half is as 17.4:100, and on the right half as 21.4:100, according to Cunningham’s method. This index averages 20.8 for human adult males, and 21.7 for females; and it increases as we descend to the anthropoids and apes. The following are Cunningham’s figures :

Orang	23.2
Chimpanzee	24.2
Hamadryas	24.5
Cynocephalus	29.7
Mangaby	30.5
Macaque	31.
Cercopithecus	32.9
Cebus	33.1

It was recognized as being of considerable importance by even so early an observer as Gratiolet, and it would seem to indicate, other things being equal, that relative smallness of the cuneus, measured in this manner, signified superiority. Its exemplification upon the better developed left half of both of the Seguin's brains would seem to lend force to this hypothesis.

Notable for its extent and well-marked course is the exoccipital fissure on the left side. (Fig. 2.) It begins very near the zygon of the paroccipital, at its caudal part and separated from it by a narrow (3 mm.) "deuxième pli de passage." Morphologically speaking, therefore, the fissure falls into the first class of Wernicke's descriptions,⁵ a condition occurring normally in some apes. As the fissure passes ventrad a notable fact is the nature of the slope of its walls, which, as in the right half, incline distinctly caudomesad. It resembles a cleft rather than an ordinary fissure, and in its depths can be seen several interdigitating subgyres. As the fissure approaches the ventro-lateral border it takes an abrupt caudal direction and terminates just at the border. Around this end curves a narrow "quatrième pli de passage." The "troisième pli" may be any one of the several interdigitating subgyres alluded to above.

Upon the right half the "troisième pli" instead of being totally submerged, approaches to within 7 mm. of the surface and is capped by the lip of the poma (occipital operculum), so that it may properly be termed a subgyre. The exoccipital fissure consists, therefore, of two segments, a superior (EOP') and an inferior (EOP''), superficially confluent with each other.

In both hemispheres the occipital lobe exhibits a distinct tendency to overlap the parietal gyres; the walls of the exoccipital fissure slope distinctly mesocaudad, suggesting the pomatic homology and derivation of the occipital lobe.

The insula on the left side is far better developed than its fellow on the right half, corroborating the statement made by Waldschmidt,⁶ that in educated men the left insula is "incomparably richer" in its development than the right. Upon close inspection, and by means of soundings made in the sylvian cleft, this redundancy is found to be most marked in the preinsular region.

BRAIN OF DR. EDWARD C. SEGUIN.

The autopsy upon the younger Seguin took place on February 21, 1898, and was made by Dr. J. S. Thacher, assisted by Drs. J. Arthur Booth and E. C. Spitzka. Drs. Hallock and Pooley were present. The brain was

removed about 30 hours after death, also by Dr. E. C. Spitzka, my father, and to him I am indebted for the opportunity of studying and describing both of these valuable brains, unprecedented in so far as I can find no other instance where the brains of father and son were available (both being of marked characteristics) and the nearest approach being the case of the brother Leidy, of Philadelphia, undescribed as yet—and a present in the collection of the Anthropometric Society of that city.

The appearance and texture of the younger Seguin's brain were normal. After dissection draining the total weight was 1,502 grams, or 52.98 ounces. The parts of the brain while still fresh weighed as follows:

Right hemisphere	642 grams.
Left " "	653 " "
Cerebellum	140
Isthmus	67

Total 1,502 grams.

The brain was again weighed on December 3, 1900 after nearly 3 years immersion in for maldehyde solution

Right hemisphere	555 gram.
Left hemisphere	563 " "
Cerebellum	109 " "
Isthmus	57 " "

Total..... 1,284 gram.

The loss in weight amounted to 21 grams, or 13% of the original weight.

This brain-weight (53 ounces in round numbers) is about 12 ounces, or about 12 grams above the average for one of Dr. E. C. Seguin's

age and height, and his position in the list of brain weights of eminent men is comparatively high.

Owing to the excellent preservative qualities of for maldehyde, this brain is only slightly flattened, and the shrinkage amounts to very little. As in the father's brain there is a slight but unquestionable exposure of the left preinsula. The left sylvian fissure more nearly approaches the horizontal, and there is a similar amplification of the frontal lobes characteristic of the father's brain. The indices of the lobes are:

Left hemisphere:

Frontal index	61
Parietal index	23.6
Occipital index	15.3

Right hemisphere:

Frontal index	57.2
Parietal index	23.8
Occipital index	16.8

The relatively small index of the occipital lobe is particularly noteworthy in both halves of this brain.

The left separation and right continuity of the parietal-paroccipital fissures spoken of in the father's brain are in the son's brain reversed as to sides. O

FIG. 3.—View of the occipital regions of both hemispheres of Dr. Edward Seguin (father). On the left a distinct paroccipital isthmus (PAROC' ISM) separates the parietal from the paroccipital; on the right these fissures are confluent over a vadium at a depth of 11 millimeters.

the right side a well-marked isthmus separates the fissures, on the left they are confluent over a vadium.

On the right half the exoccipital fissural complex does not differ very much in its appearances from the left half of the father's brain, except that the "troisième pli" is flush with the cerebral surface and not submerged.

The left insula as in the father's is far better developed than the right, and the preinsular portion is so redundant that the surrounding opercular parts have been crowded apart and a small triangular portion of the insular pole is thus made visible upon the lateral aspect.

If one be permitted to indulge in such an expression I would say that the *physiognomy* of each of these brains reproduces that of the other, much as the outer physiognomy of their bearers did in life. By the metaphoric term "physiognomy" used in this connection, I mean the general feature of the arrangement, relations and molding of the convolutions, difficult to describe in so many words and renderable only through photographic or other reproduction, and even through these imperfectly. Every brain I have yet examined had its distinct features, as much distinct as the outer ones of its owner. One may distinguish brains resembling each other as a group, and as distinguishable from other groups as are different families and races of men. No more striking instance of a prevailing typical difference can be adduced than that of the Mongolian brains recently studied by Dercum and others. It were futile to attempt basing a discrimination on any single factor. It is the general physiognomy that seems to be so peculiar to the race, but by this I do not mean that given a certain brain an investigator could declare it to belong to such and such a race or sex. We are not advanced far enough for that yet, if we ever attain such a point; and how mistaken we may be in regard to the outer features I need not remind the reader. We are much like the traveler who merely touching the shores of a new land is struck by the, to him, strangely and strikingly uniform character of a new race—yet whose individuals are as distinguishable to their fellow-tribesmen as that traveler's companions are to him.

Perhaps the most significant feature common to both brains is the exposure of the insula, and although this feature formed the theme of a special paper⁷ a brief summary thereof may not be out of place here.

Heretofore it was only in the brains of deaf-mutes, of negroes, of idiots, and of the defective classes generally, where the opercula are commonly atrophied, that the insula has been found visible. It was therefore regarded as an indication of inferior development. The brains of the Seguins, however, present the very reverse of low form or defective type. Nor are the opercular regions at all defective, though they fail to come into typical apposition. The explanation of this anomaly is that the left preinsula is far better developed than its fellow on the right side, corroborating the findings of Waldschmidt (in 1887) upon the brains of two professors of the University of Freiburg. But in the Seguin brains this redundancy of development upon the left side is so pronounced, that the insula in a *quasi*-struggle to reach the general cerebral surface, has virtually thrust apart the opercula and made itself visible.

The interpretation of this exposure as due to the relative hypertrophy of the insula is sustained by the results of "soundings" taken at various points, and given in millimeters in the following table.

The terms pre-, medi-, and post-insular depth refer to

the three points at which the Sylvian cleft was sounded, the preinsular point being the junction of the Sylvian with its presylvian ramus, the medi-insular point being at the middle of the course of the Sylvian, the postinsular being at the junction of the Sylvian cleft with its episylvian ramus.

DEPTHS OF THE SYLVIAN FISSURE IN THE FOUR HEMI-CEREBRUMS OF THE TWO SEGUINS.

EDOUARD SEGUIN (Father).

	Left.	Right.
Pre-insular depth.....	11 mm.	18 mm.
Medi-insular "	11 "	22 "
Post-insular "	24 "	22 "

EDWARD C. SEGUIN (Son).

	Left.	Right.
Pre-insular depth.....	7 mm.	15 mm.
Medi-insular "	20 "	23 "
Post-insular "	25 "	25 "

The conclusions naturally to be drawn from the above are that the causes potential in insular exposure must be discriminated or classified as follows:

Class 1.—In the highly intellectual (for example, the two Seguins), owing to the excessive growth and development of the left preinsula, causing a displacement of the opercula, thrusting them apart, as it were, and even though the latter be very well developed.

Class 2.—In the defective, exposure of the preinsula is due to deficient development of the opercula and because these fail to approach each other. In such cases the insula itself is, without a single exception in the series that I have studied, of inferior development, indicated not only by the soundings of the Sylvian cleft, but also by the flatness of configuration and lesser area of the insular cortex.

In the paper referred to, the writer said: "Among the reflections which occur in the course of such a study, is the possibility of some paternal influence exerted on the brain of the offspring under circumstances such as the following: Dr. Edouard Seguin (the father) was most actively engaged in the teaching of the idiot children at the Hospice de Bicêtre, wrote many treatises, and delivered many lectures upon the subject in the six years prior to the younger Seguin's birth. If physiological tendencies are transmitted from father to son, and if such transmission of function finds structural expression, one would expect it to be demonstrated where the circumstances are so favorable as here. Of course, all such statements are made tentatively; yet what would be a more natural conception when we view the circumstances, the visible evidences in the two brains, and the corroborative soundings of the Sylvian fissure of both sides. Both men were of high intellectual capacity; both were facile writers and speakers—if anything the son excelled the father; and both were polylinguists, speaking and writing three languages fluently. The teaching capacities of both men were remarkable, in the one case being especially devoted to the patient efforts required in the training of the feeble-minded, in the other developed in the highest degree in didactic lecturing and clinical teaching."

This unexpected exposure of the insula has been noted on both sides in the brain of Chauncey Wright, now in the care of Prof. Burt G. Wilder. In his Handbook article,⁸ written in 1889, Wilder called attention to the fact that possibly pressure may have caused sufficient displacement to artificially expose the insula. In a letter to me (March 12, 1901) in response to a communication

in which I suggested the explanation here advanced, Dr. Wilder states that probably the exposure of Wright's insula was also natural. This investigator proposes to review the matter as soon as he returns to Ithaca.

There are a number of facts which, naturally grouping themselves together, justify as a strong surmise, if not a scientific probability, this anticipation: that hereditarily transmitted and identifiable individualities in gyral disposition will be first satisfactorily determined in the region of the insula. To attempt sustaining this proposition by the experience of the single case here presented were absurd; it simply points in the direction of the following logical chain—partly of obtained facts, partly of natural conclusions from these.

In a study made of heredity, whose results were placed at my disposal, covering the parentage and descent of individuals prominent in various fields of

The speech faculty in its intimate relations to thought-expression, to memory—in its reading-form to sight, in writing to manual muscular innervation, exquisitely hereditary as it is in life, and most accurately localizable in the ravages of disease, as shown after death, appears one whose transmission is most likely to be expressed by morphological signs—be they relative and quantitative or purely morphological—and these in and about the Island of Reil.

I have said that there exists a resemblance between the "physiognomies"—if I may use that term—of these brains. But if the various features of these specimens be separately analyzed and compared this resemblance becomes a striking one. The view that a coincidence of features in the brains of parent and child is due to an actual *transmission*, as that term is now understood, gains in plausibility in proportion as such features

FIG. 4.—Lateral view of the left hemisphere of Dr. Edward C. Smith, son. Aside from the redundant development of the opercular, and the nearly horizontal course of the Sylvian fissure, the most striking feature is the visibility of the process, whose summit approaches within 7 mm. of the cerebral surface. $\times .83$ natural size. From a drawing by the author.

science, politics, art, and handicraft, it is found that the cases where both father and son attained distinction sufficiently to merit place (in the biographical encyclopedias), in intellectual fields of labor, they had been of those in which skilled motor innervations in their association with sensory impressions and registrations are prerequisites. Preeminently is this the case with two professions; that of the composer-musician and that of the philologist. As defects in speech are so likely to be repeated in a family line, it seems that its skilled employment by the ancestor is similarly reflected in the way of facile acquirability on the part of the descendant. Not unrelated may be the fact that among those recruited for the ranks of linguists of other than philologist parentage, there largely predominate those whose parents had emigrated or who were born on islands, in seaport towns or in lands where two dialects are spoken, not to mention those in whose families it has been the custom to maintain an ancient tongue for sacerdotal reasons.

are marked or exceptional, and most so, as in the brains before us, where they approach the atypical.

The term *atypical* as here used is so in a morphological sense only, and not as equivalent to the sense of aberrant atyp—heterotyp—being a grossly asymmetrical and pathological brains. Just as it is the simplest brains that are more symmetrical than the higher ones, so the simplest arrangement of gyres is also the one which is most purely and symmetrically typical. With higher development, a certain degree of deviation from the type seems an inseparable accompaniment of the luxuriant development, contorted foldings, and deep as well as complicated fissuration, which represent a struggle for surface and expansion, in which the interests of neighboring formations often balance unevenly. This irregularity is regular even in its irregularity, however; of the surface only and in this respect parallel to those perhaps not unrelated manifestations of the living organ of the mind, which in the shape of originality or ingenuity are often mis-

apprehended and interpreted as evidence of unbalancing and eccentricity. It is because the simple mind has not breadth enough that it neither indulges in excursions into a field of original thought, nor understands such when indulged in by others. So it is because there is little rivalry of growth interests in an unexpansive organ that its simple gyres repose in the rough and comprehensible simplicity of the Bechuana folds.

"To certain minds fate narrow bounds has set,
In vain they try beyond those bounds to get."

In reality all these qualities are but expressions of a strong individuality; and individuality is not conceivable otherwise than as an expansion beyond the average mediocrity,—expansion in the direction of deviation from that of the common rut.

In the case of the two Seguin brains it is safe to say that if they had been scattered among a hundred other brains, and these had been grouped according to the type of gyral disposition, they would have come together as the classification became finer and finer until ultimately they probably would have constituted a group by themselves.

The asymmetry of the halves of highly-developed brains must therefore form the basis for demonstrating hereditary transmission in the brains of parent and child before us; and it is for such unilateral features that we must search. They are present in sufficient number to establish the proposition, and while I am prepared to enumerate these at length, their presentation and discussion would require more space than it is my privilege to occupy. Briefly stated, the most important of these features common to both brains are:

The left insula exhibits an incomparably richer development than the right.

The left occipital index is smaller than the right.

The left frontal index is larger than the right.

The left subfrontal gyrus is larger than the right.

On both right operculums there is a single isolated fissure embraced by the limbs of the presylvian fissure.

The left medifrontal fissure is in two segments (in one case separated by a superficial isthmus, in the other by a slight vadium of 4 mm.). Furthermore, the medifrontal is poorly represented on the right sides.

The left cephalic limb of the paracentral fissure is short; long on the right.

The left episylvian fissure, and also the hyposylvian are longer than on the right half.

The left fronto-marginal fissural segments are easily traced; they are absent on the right sides.

The left olfactory fissure is shorter than the right.

The left Sylvian fissure more nearly approaches the horizontal than does the right.

The existence of these and other facts give strong evidence of *direct hereditary transmission*. In addition, however, there are other interesting points of resemblance in attributing which to such transmission, one strange apparent difficulty is encountered, namely: their reversed position as to sides. This "crossed heredity," or the reproduction of unilateral asymmetrical peculiarities of one side in the father's brain upon the opposite side in the son's, would constitute an interesting chapter in itself. An enumeration of the facts in support of this mode of *crossed hereditary transmission* can only be briefly made here.

FATHER'S BRAIN.

I. Left parietal f. and paroccipital f. separated; continuous on right.

SON'S BRAIN.

Left parietal f. and paroccipital f. continuous; separated on right.

II. Postcalcarine f. bifurcated on right only.

III. Right occipitocalcarine angle=70°; left 60° (circa).

IV. Father's right "exoccipital complex" almost identical with son's left.

V. Left parietal f. joins supertemporal f. and intermedial f.

VI. Mode of junction of right medifrontal f. with orbitofrontal f. exactly as in son's left.

VII. Father's right half heavier.

Postcalcarine f. bifurcated on left only.

Right occipitocalcarine angle=60°; left=70° (circa).

Son's left "exoccipital complex" almost identical with father's right.

Right parietal f. joins supertemporal f. and intermedial f.

Mode of junction of left medifrontal f. with orbitofrontal f. exactly as in father's right.

Son's left half heavier.

The last item is one to which I am not prepared to attach too much importance, for observations upon the weight of the halves of a dissected brain come within the range of error usually ascribed to the "personal equation."

The history of inheritable peculiarities, such as sex, polydactylism, abnormalities of the external ear, and the like, show that the problematical mechanism of their transmission acts without regard to any other plan, in this respect, than that of "symmetry in asymmetry;" namely, it impresses the same or similar variation from the typical, if not on both sides, on either side alone, and indifferently as to correspondence with the one parentally involved.

Any declaratory explanation for the contralateral situation of the same or similar atypy in the brains of parent and child must rest on conjecture. The influences at work in molding organic forms are profoundly mysterious; particularly is this the case where symmetrical relations are in question. I need but refer to the possible relations of this fact to the more familiar ones just referred to, such as one-sided peculiarities of the pinna, the digits, or the orbits; and that these influences act contralaterally as well as unilaterally, and as harmoniously in their inversion as in those rare cases of complete transposition of the viscera. Let me instance an authentic case of maternal impression reported by Dr. W. L. Swift (*New York Medical Journal*, October 9, 1886, p. 407), where the birthmark not only repeated the original one-sided maternal impression, but was also duplicated, both sides of the body showing it. . . . Brown-Sequard demonstrated the hereditary transmissions of lesions in the nervous system of guineapigs, the change in the descendants often being bilateral where they had been unilateral in the animals experimented upon. (*Comptes rendus*, vol. xciv, 627). The deformities of "hammer-toe" and "syndactylism" may likewise exhibit unilateral, bilateral or even contralateral transmission. Lastly, I would allude to the mirror like reproductions of physiological and pathological phenomena on opposite sides in certain forms of hysteria.

If such modes of transmission be wonderful and mysterious how much more so is that of the hereditary influences of which we speak. When we remember that we are dealing here with the one organ of the body that is so variable that no two individuals possess it exactly alike, so far as external appearances are concerned, the importance of determining as nearly as possible the influences of heredity will be understood readily enough. More material of this kind, and extended observations upon this line are necessary before we can arrive at any satisfactory conception of the external appearances of this most important organ. Anatomists and scientists

in general cannot urge too strongly upon their fellow-men and women the importance of bequeathing their brains to the uses of a science which might well regard such bequests, if not as invaluable as the legated brains once had been to their original owners, of the very highest one, such being indispensable to progress in psychological physiology.

For valuable aid and information cheerfully given while pursuing this study, the writer wishes to express his sincere thanks to Mrs. E. M. Seguin, and to Drs. J. Arthur Booth, E. Leaming, and Professor B. G. Wilder.

SANTIAGO AS A YELLOW FEVER CENTER.

By MAJOR L. C. CARR, Surgeon, U.S.A.

Chief Surgeon, Department of Eastern Cuba.

In 1898 I frequently heard the statement made, that for many years Santiago de Cuba and Santos, Brazil, had been in a class of their own, universally accepted without question as the two filthiest and most unhealthy cities on the globe.

The death-rate here given for Santiago is made from records for the years 1888-1897, both inclusive; they were compiled by Dr. M. J. Rosenau, Marine-Hospital Service, who says in submitting his report:

"SANTIAGO DE CUBA, May 8, 1899.
 "Sir—I have the honor to transmit herewith mortality statistics for the city of Santiago de Cuba during the past ten years. These interesting figures were kindly collected for me by Sr. Eduardo Yero, the Alcalde's clerk, after much searching through musty records. The figures were taken from official reports."

It is fair to presume that these records are faulty, and that the number of deaths given is less than those that occurred. The population of Santiago during these years can be only approximately determined, after exhausting all sources of information. I have taken 45,000 as a standard, upon which the following calculations are based:

Year	Smallpox	Tuberculosis	Yellow Fever	Pernicious Fever	Fever other than Yellow and Pernicious	Other Diseases	Total	Death-rate per Thousand
1888 . . .	4	139	151	109	53	701	1157	25.97
1889 . . .	7	139	131	11	86	702	1157	25.71
1890 . . .	2	124	51	58	44	730	1009	22.42
1891 . . .	1	169	119	13	149	913	1354	30.53
1892 . . .		125	6	96	14	817	1059	23.42
1893 . . .	0	100	4	57	70	911	1137	25.27
1894 . . .		132	55	13	68	711	1031	22.91
1895 . . .		111	101	241	306	1451	2110	46.44
1896 . . .	559	316	206	177	477	1845	4012	89.15
1897 . . .	4	410	225	229	128	2001	4497	99.93

During this period it will be noted that tuberculosis and yellow fever caused about one-fifth of the total deaths, also that the death-rate for 1895, 1896 and 1897 is abnormally high, even for a filthy tropical city; this rate reached an alarming height in 1898. The statistics for 1898, 1899 and 1900 are fairly accurate; yet there can be no question but that there were many more cases of yellow fever in Santiago during 1898 than were officially reported, and also, that during July, August and September of that year the population was well over 45,000, but the confusion owing to the campaign is responsible for lack of data.

Year	Smallpox	Tuberculosis	Yellow Fever	Pernicious Fever	Fever other than Yellow and Pernicious	Other Diseases	Diagnosis Unknown	Total	Death-rate per Thousand
1898 . . .	1	415	20	428	181	29	1179	2053	45.71
1899 . . .	1	171	10	107	100	801	4	1394	30.75

Tuberculosis attracts but little attention here. The same remark applies to yellow fever, so far as natives are concerned, and yet the natives suffer from the former, while free from the latter; their constitutions are accepted as a necessary evil, and judging from my experience here during a period of 28 months, 80% if not more of the population are subject to recurrent attacks.

In the tables will be noted deaths under the heading "diagnosis unknown"; this is a relic of past carelessness, which will not be permitted in the future.

With all of her drawbacks, the Santiago of today is very far removed from the Santiago of 1898: her principal trouble at the present time is malaria, which prevails in all of its forms, but it is not so serious as formerly, nor is the pernicious form found so frequently. With the exception of eleven cases of diphtheria, from which disease we are now free, there have been no contagious or infectious diseases this year.

Incomplete as the records are, they show yearly visitations

of yellow fever; these records can be traced to the year 1840. It is within reason to say that yellow fever has existed here continuously for over 100 years; many of these annual visitations were epidemics and were very severe, but the data obtainable are too unreliable to quote.

The fever has frequently visited El Cristo, 10 miles, and San Luis, 26 miles north, also Palma Soriano, 42 miles northwest; all of these points are about 650 feet above the sea level. On the east, Guantánamo has had many visits; the city is 14 miles from its harbor, Caminera; little hamlets within a radius of 15 miles of Santiago have also reported frequent visitations. Santiago never having been free from the disease, was always considered the source of infection. The results this year establish the justness of the claim, for while no such precautions were taken at other places as were taken here, there was no yellow fever within 150 miles of Santiago.

The Provinces of Santiago and Puerto Principe comprise nearly one-half the extent of the Island, and the following harbors, large and small, are on their sea-coasts: Nuevitas, Puerto Padre, Banes, Gibara, Mayari, Sagua de Tanamo, Baracoa, Guantánamo, Santiago, Manzanillo, Santa Cruz and Jucaro. These harbors are visited by vessels of all sizes from every part of the world.

During the year of 1900, the following has been the report from Nuevitas in the Province of Puerto Principe:

Three cases of yellow fever occurring as follows:

The first, a Spaniard, on April 14, 1900; the second on April 27; this case I saw on May 6, and did not agree with the diagnosis; it was the case of a discharged soldier who had been on a prolonged spree; my diagnosis was acute alcoholism, with malarial complications and a prognosis of a fatal termination; after results did not bear out a diagnosis of yellow fever. A sporadic case at that season of the year was out of the question: it was the time for an epidemic; the season of the year, climatic conditions and materials were there—nonimmunes from La Gloria, discharged soldiers and newly arrived Spaniards to the number of 90—and no other case was reported until June 21, 55 days later; this latter case was also a Spaniard, and a study of the temperature, pulse and symptoms which had been received by telegram and from which a chart had been made, made a diagnosis in this case by no means certain. Cuban physicians, as a rule, are not accustomed to meeting cases of drunken and worthless fair-skinned foreigners who may be taken sick from the effects of alcohol, climate and neglect; such cases have been frequent since American occupation (and noticeably, drunkenness is not a failing of the Cuban race). Given such a case as above stated, you have a congested face, violent frontal headache, congested eyes, jaundice, epigastric tenderness, vomiting and nearly always albumin, all of which are pronounced symptoms of yellow fever; add to this malarial complications, and a diagnosis of yellow fever is easily made.

HOLGUIN.—The town is situated about thirty miles from the coast; yellow fever had not visited there for several years; on May 17, 1900, a case was reported, an American six months on the Island, the last two months of this period spent in Holguin, from which place he had not been absent during that time. He reported to the post surgeon sick, was admitted, and six days after admission a diagnosis of yellow fever was made. Symptoms, temperature and pulse-rate, three observations were asked for by wire; from these telegrams a chart was made; a study of that chart and the fact that in the face of exposure from this patient and the place of his supposed infection no other case occurred in Holguin, rendered the diagnosis in this case extremely doubtful.

On October 13 a Spanish passenger from Havana took sick on the Steamer *Julio* three days out from Havana; he was left at Gibara, the diagnosis was yellow fever; all precautions were taken against its spread. The case resulted fatally; of this case I have received no data; there were no other cases.

In all, four cases have been reported as occurring in these two provinces, three in Puerto Principe province and one in Santiago province, one was not yellow fever, and in the three other cases there was sufficient reason for doubt.

I give in *extenso*, tables for 1898—1899 and for 1900 to October 31.

MORTUARY STATISTICS—SANTIAGO DE CUBA.

(Based on a population of 47,000)

YEAR 1898.

BIRTHS FOR OCTOBER, 1900.

MALE.		FEMALE.		TOTAL.		Average.
White.	Colored.	White.	Colored.	Male.	Female.	
11	22	13	13	33	26	59

This is the first month in which the above statistics have been kept.

For 1900 the vital statistics are given in more complete form, showing the changes that American methods have made in the manner of their keeping; all of these changes are new innovations, and much time and labor has been given to introduce them and accustom physician and officials to their use.

The following tables are self-explanatory, and the consideration of the generally accepted theory, that heat and moisture under certain conditions have a definite influence on the propagation of yellow fever, gives to these tables a peculiar interest.

In accordance with that theory, other things being equal, the season of the year 1900 was far more favorable for a yellow fever epidemic than the season of 1899.

For ten days preceding June 15, 1900 (date of outbreak in 1899), the temperature was higher with slightly less moisture than for the same period in 1899, and for the ten days following June 15, the temperature was higher, and there was a greater rainfall in 1900 than in 1899.

From the 11th to the 20th of June, 1900, both dates inclusive, the maximum was but once below 90°, and the minimum ranged from 75° to 77°, dropping to 74° but once in that period, June 18th.

The height of the epidemic in 1899 was in July. During July of 1900, the maximum temperature was 1.1° higher and the minimum .3° lower than in July, 1899. The precipitation was .03° higher in 1899 than in 1900.

MAY, 1899.

Manson on tropical diseases, voices the accepted view of experts, when he says:

"For its development in epidemic form, yellow fever requires a temperature of over 75° F. It ceases to extend its area when the thermometer sinks below this point, and it stops abruptly as an epidemic when the freezing point is reached; although—as proved by the recurrence of the disease two years in succession in one of the Spanish epidemics, and that without a fresh introduction—the vitality of the germ may not be extinguished and killed outright by frost. Dampness favors yellow fever; it is therefore most prone to occur during the rainy seasons.

"Conditions of soil required.—Further, it is not every spot that affords the extracorporeal conditions demanded by the germ. It would appear that an admixture of animal matter must enter into the composition of the nidus; decomposing vegetable matter does not suffice."

If this means that a case of yellow fever must exist, before these conditions will have any effect in causing an epidemic, I have not been so taught. In a city wherein yellow fever is due to importation, a case must be brought before any meteorological condition can be considered as bearing on its spread. It is also true that these conditions are co-existent with an epidemic of yellow fever.

But how apply such theory here where the disease has been endemic for years, and is also presumably indigenous? Must importation also be had?

I have until now always believed that such weather was the one thing necessary to cause an outbreak of yellow fever in a city wherein the disease was endemic, if the other requirements were there and the nonimmunes were present.

A study of the tables given, and consideration of conditions existing at Havana and Santiago, indicates that the theory is fallable.

Here we have two cities wherein yellow fever has been endemic for many years: Havana in 1899, from May to October, both months inclusive, had a mean temperature of 79.75, precipitation 17.23, cases of yellow fever 163, deaths 59. For the same period in 1900 the mean temperature was 79.49, precipitation 26.71, cases of yellow fever 916, deaths 215.

For the year 1899 the immigration was 16,260, for the 10 months ending October 31, 1900, the immigration was 16,859.

For the same 6 months, Santiago in 1899 had a mean temperature of 81.13, precipitation 37.03, cases of yellow fever 235, deaths 53; and for the same period in 1900 the mean temperature was 81.68, precipitation 49.41, and no yellow fever.

In 1899, Santiago had a nonimmune population of from 1,300 to 1,500. In 1900 the nonimmune population was over 1,300.

All of the conditions required by the heat and moisture theory were present in both cities. Havana had a higher mean temperature in 1899 and less of a rainfall than she had in 1900; the difference in the epidemic can be seen.

Santiago had a higher mean temperature and a greater rainfall in 1899 than Havana had in either year cited, and in 1900 Santiago's rainfall was much greater and her mean temperature higher than in 1899.

It seems to me that in view of these facts, the theory that heat and moisture play the all important role in the development of yellow fever, must fall, and the admission only granted that these conditions are coexistent with an epidemic of yellow fever.

The deductions made from his observations by Touatre in New Orleans cannot apply to conditions here in Santiago, for the reason, it is affirmed, that when yellow fever appears in New Orleans it is due to importation. Here it is endemic.

It would be egotistical to assert that our work here was the sole cause for the nonappearance of yellow fever in 1900, especially after the severe epidemic of 1899. Also, to further assert that the sanitary work done in Havana had been a failure would be pessimistic.

I have endeavored to obtain data from Kingston, Jamaica, for comparison with conditions existing here, but it is difficult to obtain official information. On November 11th I had the good fortune to meet Mr. Goldsmith Williams, of the Cuba Fruit Company, a gentleman of keen observation who has lived much and traveled extensively in the West Indies; from him I gathered the following facts:

He thinks that until 1897 Kingston was nearly as filthy as Santiago. He described the open sewers in the streets and characterized the odors as unbearable; the older and business portion of the city, he said, was built much similar to Santiago; climatic conditions were almost identical; they do not fear yellow fever, and until 1897 they took no precautions other than quarantine against infected ports. The disease has never been considered endemic there. The inhabitants attribute their safety to the trade winds which blow steadily over the city for from 10 to 14 hours daily; so much are they impressed with the truth of this that the trade winds are called their doctor.

After the epidemic of 1897 the sewer system was completed, and since then Kingston has been in a much better sanitary condition.

Jamaica is 80 miles south of here, and Kingston is on its south coast; in all, about 140 miles from Santiago, a little west of south. The letter here given contains all the official information I have been able to obtain:

British Consulate,
SANTIAGO DE CUBA, July 12, 1900.

Major L. C. Carr,
Chief Surgeon, U. S. V.,
Santiago.

Sir:—I have the honor to inform you that I have just received under date 25th of June, an answer from the Superintending Medical Officer, Jamaica, to my enquiry of April, regarding yellow fever epidemic in Kingston, and which is as follows:

"I have the honor to acknowledge receipt of your letter dated 11th April last, and, in reply, to inform you that the records at my disposal do not go further back than the year 1879, from that date to the year 1899, with the exception of 1 or 2 sporadic cases at long intervals, there was no yellow fever in Kingston.

"In 1897 we had an epidemic when 72 cases were recorded, since then Kingston has been free from yellow fever.

"I regret that a press of work and other matters have prevented my replying to your letter earlier."

I am, sir,

Your most obedient servant,

(Signed) ROB. MASON,

Consul.

Mr. Williams further informed me, that in 1897 the authorities claimed to have located the first case of yellow fever. The patient was a man who had left an infected port of Central America a short time before. The authorities agreed that this case was responsible for the epidemic, which they asserted was due to importation. I give this statement without comment.

The question here raised as to the part played by heat and moisture in the development and propagation of yellow fever, is worthy of more study than has been given to it in the past. It appears to me that too much has been taken for granted.

Consideration of the obstacles that were encountered, and the steps taken to overcome them, may enable the reader to arrive at a conclusion as to what fact or factors we owe our escape.

1. Meteorologically, the conditions existing in 1900 were more favorable for an epidemic of yellow fever than the conditions which existed in 1899.

2. Food for the fever.

A careful census made by First Lieutenant Edward F. Geddings, Assistant Surgeon, U. S. A., and Dr. Richard Wilson, Acting Assistant Surgeon, U. S. A., shows that during the dangerous period, from April to October, we had a resident and floating population of over 1,300 nonimmunes, and the greater majority of these were of that dangerous class—migratory loafers. This condition varies very little from that of 1899.

3. Owing to the style of architecture, the manner of construction and the crowding together of the buildings, disinfection by fumes or vapors was out of question.

4. There were 41 distinct foci of infection in the city and 12 in the outskirts and small towns adjoining; these were known. It was the unknown points that were feared.

5. The residents, being immune, have no fear of yellow fever, consequently their carelessness, and in many instances their resenting of American methods of sanitation, made our work very difficult.

6. The custom of the people, throwing urine and other filth into the streets was an element of grave danger: this practice has not been overcome, nor will it be until a system of sewerage shall have been established.

7. Our limited water-supply has made our work very trying; at this writing it is the best we have ever had, 5 gallons per capita. During the dangerous season it was very much less, and but one-fourth of the city was supplied at one time, the average being 18 hours of the 24 without water.

8. The privy system here is abominable; many of the old vaults had not been cleaned for over 50 years. Their location adjoining kitchens and cisterns rendered them very offensive and extremely dangerous. Butcher shops, bakeries, and groceries, were invariably found to be in bad condition. In the bakeries horses were found in stalls adjoining ovens, and seepage of decomposing urine into the work rooms was the rule, some mixing rooms were found covered with living filth; butcher shops and groceries with piles of rotten offal in back rooms and patios; but, nevertheless, this class of people have been found amenable to reason when shown the way.

9. Owing to the fact that we had an inadequate water-supply, the newly laid sewers had not been in use and the manholes along their course would fill rapidly and become very offensive and dangerous.

10. I feel constrained to here call attention to the most serious among the obstacles that were encountered:

The evident and expressed wish of the Marine-Hospital Officer that we should have yellow fever here.

His printed circular prior to April 1, 1900, which had the full force of an order, driving all of the army ladies out of the country.

His curt refusal to cooperate with the military and civil authorities.

His strenuous endeavor to prevent our having a quarantine against Havana.

His public and written statement that we would have yellow fever here, the only question being in which month it would develop.

His prophecies and public utterances, all of which were a grave reflection upon the service he represented.

Circular Letter No. 3, Headquarters Department of Santiago and Puerto Principe, March 30, 1900, by order of Colonel Whitside, contains this paragraph:

"All cases of contagious or infectious diseases, or suspected to be such, shall be reported to the President of the Board (Chief Surgeon's Office), who shall immediately notify at least three members of the Board to examine and decide the nature of each case so reported. The opinion of the examining members shall be expressed in writing over their signatures and handed to the President of the Board.

"No case of contagious or infectious disease shall be officially recognized except when reported by the Board of Health."

In direct opposition, he endeavored on April 23, to place in our yellow fever hospital, over which hospital he had no control, a case diagnosed by him as yellow fever; this endeavor on his part created great consternation in the city; a committee of four physicians visited the sailor, who was then in the eighth day of his sickness, diagnosed the case as typhoid fever, sent the patient to the Civil Hospital, and so reported to the Department Commander.

This act resulted in his recall; that it was his first official experience in a position of command, that he had only a superficial knowledge of yellow fever and that he was a youth, may be offered in extenuation.

The Marine-Hospital Service knew that Santiago was a station of great importance; also one entailing grave responsibility, and it has too many well equipped officers and gentlemen in its corps to have permitted, even for a day, such conditions to exist after the facts were brought to its knowledge.

Dr. M. J. Rosenau, who preceded the officer referred to, on duty here, was thoroughly equipped, did his work carefully, effectually and without friction, and was always a gentleman.

So with Dr. R. H. von Ezdorf, the present incumbent, who succeeded him; coming, as he did, into an atmosphere of discontent, distrust and general misunderstanding, he cleared it in a remarkably short space of time, and won the confidence and respect of all with whom he came in contact. This report shows what our success has been and much of the credit belongs to Dr. R. H. von Ezdorf, who in addition to his other qualities is an untiring worker.

To a station of such importance the Marine-Hospital Service should detail only of its best officers, for competent and gentlemanly medical men will always work in harmony with other authorities when the object is the greatest good for the greatest number.

I have weighed this matter long and carefully before concluding to make these facts public, but the gravity of the situation, the possibility of a similar happening, the powers for good or evil that lie in the hollow of one man's hand when appointed to such a post by the Marine-Hospital Service have outweighed all other considerations.

STEPS TAKEN FOR A PREVENTION OF AN OUTBREAK.

1. TRAMPS.—Recognizing the danger from this element, among whom yellow fever usually makes its first appearance, and fully aware of the utter hopelessness of locating the foci when such people would be attacked, an effort was made to reason with them to protect themselves while protecting the city; work was found on roads, buildings and in the iron mines, and on May 25, some 68 of the most dangerous were arrested; 40 were Spaniards, 3 Americans, 8 Jamaicans, and the rest of various lands.

The Spanish, French, and English Consuls, all in thorough accord with this movement, in company with the Chief Surgeon, visited them and matters were fully explained; 11 of them were sent to the hospital and 57 were instructed to call at an office where a clerk was kept on duty all day distributing them to places as seemed suitable; the next day 4 of the 57 called for work. In June another effort was made; about 60 were arrested and told that there was work for 50,

but that it was not compulsory; only 5 of the number agreed to work. The Department Commander then authorized the Alcalde to have them arrested under the Spanish tramp act, as vagrants. This form of arrest began July 1, 1900, and arrangements were perfected to rid the city of this dangerous element. They caused us more or less trouble during the entire period until October 31.

2. On March 1, 1900, the general re-disinfection of the foci began with a trained force, under the direct control of an experienced and capable chief. The disinfectant used was corrosive sublimate (strength $\frac{1}{2}$ pound to 50 gallons of water with the addition of $1\frac{1}{2}$ pounds of salt to a 50-gallon barrel).

Force pumps were used on wells and ceilings, and floors were scrubbed and drenched; where the force pump could not reach, swabs were used. This disinfection was completed by July 1, 1900. All of these places were re-disinfected; some of the filthy houses, 3 or 4 times, and cafés, lodging houses, and resorts frequented by non-immunes, every 3 or 4 weeks.

3. A careful watch was kept over the town. The indiscriminate throwing of filth into the streets was in a measure prevented, and it was only permitted at a stated hour, while not avoiding, this requirement lessened the danger. It was Hobson's choice.

4. Our limited water-supply is a proposition upon which the Engineer Department is still at work.

5. About 500 latrines were found to be in a dangerous condition; the records of the Sanitary Department show that of this number, 350 were cleaned or contract made for their cleaning. On June 22, the second inspection began of places reported dangerous on the first inspection; a list of houses with owners and tenants who had failed to comply with the sanitary regulation was submitted to the Alcalde with request that these parties be proceeded against at once in accordance with the regulations. The inspection showed that the most dangerous part of the city is the district bounded on the north by the Paseo de Concha, the south by Marino, the east by Gallo, and the west by Cristina streets, which is owing to the fact that this section receives all of the ground wash of the entire city and the privy vaults here are constantly filled to overflowing. The regular force of vault cleaners were not enough for the increased work made by these inspections; therefore, many of these contracts were sub-let to contractors whose work has proved very satisfactory. In pursuing this work, a remarkable condition has been presented, which it is hoped is only a local and not a general characteristic of the people of Cuba; the poorer and uneducated classes have offered no objections and where poverty did not absolutely prohibit, obeyed the instructions of the inspectors as best they could. *Per contra*, many dangerous places were found belonging to and inhabited by the people of education, refinement and wealth, a number of whom had traveled extensively abroad, representing the different professions and belonging to the best families in the city; several of such have not only positively refused to clean their homes, but have been discourteous and insulting in their refusals.

6. The manholes referred to were pumped out every day and arrangements were made to thoroughly disinfect them after every pumping.

In all of this work, the Department Commander, Colonel Samuel M. Whitside, took an active interest and was in hearty sympathy with all efforts to this end; his suggestions as to ways and means were ready and valuable, and he always accomplished measures recommended by his Chief Surgeon in the shortest possible time and with but little or no friction.

For an officer so long connected with purely military duties to quickly grasp and thoroughly comprehend the manifold difficulties solely sanitary and altogether civil was an agreeable surprise to me, and it is beyond question that without his earnest support and advice results here given could not have been obtained.

The Cuban, from a sanitary standpoint, is of a class with which the American sanitarian is not familiar. The manners, creeds and customs of his forbears are to him sacred; any attempt to improve his sanitary condition that conflicts with his inherited beliefs, is regarded as bordering on sacrilege.

Santiago as a home of yellow fever was part of his heritage; that existing conditions affected the future of the people,

crippled the commerce of the island, endangered the lives of others and retarded the growth of his city, did not appeal to him. He was immune and had no fear.

The following from the *New York Medical Record*, page 20, July 7, 1900, shows this feeling:

El Cubano, an Havana newspaper, recently revealed one of the reasons for this opposition. It said, "the Cubans justly and properly object to the expenditure of such a large proportion of the revenues of the island in measures intended to repress yellow fever, for the only result of such measures is to protect the lives of the Americans, since the Cubans themselves are immune from yellow fever."

Spanish law is admirably fitted to interfere with sanitary procedure, and its aid was frequently invoked by people of the better class, when they thought that the health regulations being enforced were interfering with their personal comforts or desires.

My observations, covering a period of 28 months, have led me to the conclusion, that for some time to come the people of this island will not be prepared or inclined to take hold of sanitary measures, and therefore whatever Cuba's future may be, the United States will be culpably negligent of her own interest, of the interest of her southern States in particular and of the world in general, if she permits health regulations, sanitary measures and quarantine restrictions to pass from her control before she is convinced that these matters are thoroughly understood and will be faithfully and intelligently prosecuted by the people of Cuba.

Wasdin says in his conclusions (*The Journal of the American Medical Association*, October 6, 1900):

"That the bacillus icteroides is very susceptible to the influences injurious to bacterial life, and that its ready control by the processes of disinfection, chemical and mechanical, is assured."

This statement will not be questioned, as it is one of the few points in connection with yellow fever that admits of no dispute.

Even in a filthy tropical city, without proper sewerage, without any sanitary standard whatever, the work of disinfection can be pushed to a successful issue.

This fact is fairly in evidence; the foci of yellow fever are in certain definite places in a city where it is endemic. The habitat can be located and as fast as one appears it should be guarded closely, and with all of its belongings, disinfected thoroughly, and, as an added precaution, redisinfecting at intervals during the danger period; these places should be kept under continual surveillance and treatment and no pains or expense should be spared to render the contagion at such points inert.

I am further convinced that our work in Santiago did much to ward off an attack, and yet this question intrudes itself, were there not many foci that escaped us? That there were is undoubtedly true; but we took care of all that were of record and were prepared for any new ones that might appear.

There is still much in connection with meteorological conditions and nature of nidus necessary for the propagation of this scourge that we do not clearly understand.

Nearly all of the best men, men of scientific attainments who have had practical experience in the care of yellow fever, and in the sanitation of cities wherein the fever was epidemic, are now engaged in laboratory work, endeavoring to demonstrate which germ is responsible for this scourge. We all must admit that the object is a most laudable one and our hope is that it will soon be determined beyond all doubt.

But would not the interests of humanity be better served if the sanitary measures in the cities wherein yellow fever is endemic, were under the constant watch and control of some such men?

After an epidemic, this important work—looking to a prevention of a recurrence—is often left in the hands of inexperienced and careless persons. Why should not some of these men devote their entire time and attention to preventive measures, giving intelligent supervision to methods that we have, and know to be reliable?

Before closing I wish to call attention to the work of First Lieutenant Ira A. Shimer, Assistant Surgeon, U. S. A., as Sanitary Inspector. He enthused the whole force with his energy and personally supervised all details. He satisfied himself by personal inspection that all work outlined was

being faithfully performed. During his absence on leave, this work was in charge of Acting Assistant Surgeon Milton Vaughan, U. S. A., who carefully directed its prosecution. First Lieutenant Edward F. Geddings, Assistant Surgeon, U. S. A., was on duty in connection with contagious diseases, his knowledge of yellow fever and the methods of its handling, made him especially valuable at this time.

I desire to express my thanks to Major Valery Havard, Surgeon, U. S. A., Chief Surgeon Division of Cuba; Major William C. Gorgas, Surgeon, U. S. A., Chief Sanitary Officer of Havana; Assistant Surgeon R. H. von Ezdorf, Marine-Hospital Service; and also Mr. A. V. Randall, of the Weather Bureau, for data, from which these tables have been compiled, and further to thank the officers of the Departmental Staff for their unvarying courtesy and the assistance rendered me whenever it was required.

November 26, the date of completion of this paper, 11 months have passed, during which Santiago has been free from yellow fever.

Under these conditions the possibility of a case occurring in December is very improbable.

A CORRELATION OF SOME FACTS IN THE PROPAGATION OF YELLOW FEVER, WITH THE THEORY OF ITS CONVEYANCE BY THE CULEX FASCIATUS.

By H. R. CARTER, M.D.

Surgeon United States Marine-Hospital Service.

UNTIL the life-history of the *Culex fasciatus* is worked out it is not possible to fully compare with the theory of the conveyance of yellow fever by this agent as a host with such facts as are known of the propagation of the disease.

Still it seems that a correlation of some such facts well established and generally admitted with the above theory may be of interest.

First.—Yellow fever is not transmitted directly from the sick to the well. It is propagated from the sick man by his infecting his environment, from which it is contracted by others exposed thereto.

Second.—Certain conditions of environment are necessary for it to become infected. Besides temperature and moisture, there are others of which we are ignorant, and many localities habitually have not received infection from the presence of the sick, although there are no differences in climate, which we could appreciate, between these localities and others that did so become infected.

This quality of a place, its being infectible by yellow fever, sometimes, probably frequently, varies from year to year. Cases of yellow fever may be introduced some summers with impunity and in others in the same place spreads on introduction.

From the first a necessary deduction is that the disease is not propagated by material conveyed directly from the sick to the well; that some material after leaving the body of the patient undergoes some change outside of his body, and after this change produces yellow fever in one susceptible to that disease.

This change, which takes place outside of the body of the sick man, may be:

A. A change in physical condition of the excretion containing the microorganism rendering it able to reach the proper atrium for the infection of others. Analogous to the drying and pulverization of tubercular sputum, etc., etc.

B. The infection of a host, by which host (or its offspring) the microorganism is transmitted analogous to the transmission of malarial fever, or the Texas fever of cattle.

C. A change in the microorganism itself; it undergoing development outside of the human body into some stage different from that in which it leaves the body.

This last has been the theory accepted by most of the writers who have considered this subject, but there is no analogy with the propagation of any other disease, so far as is known to the writer.

So far as postulate first is concerned the conveyance of yellow fever by this mosquito as a host is perfectly consistent with it.

As for postulate second this theory would make an environment "infected" if infected mosquitoes existed there, and "infectible" or its reverse as the *Culex fasciatus* was present or not. If an investigation shows its absence (or general absence) in noninfectible localities and the converse it would be very strong corroborative evidence.

I am informed that this mosquito was abundant the past fall in Washington, D. C., a place usually considered (although for not sufficient reasons) a noninfectible one.

To the above two postulates the writer is inclined to add a third one, viz., "that a certain period of time, from the exposure to the patient, is necessary for an environment to develop infection."

But while this is supported by a good many observations, and is he believes true, yet it is not universally admitted, as are the other two. It will, therefore, not be considered on the basis of an admitted postulate.

The theory of the mosquito host is also perfectly consistent with this—as are both of the other two theories of infection.

Third.—Infection may apparently be retained a long time by an environment without a reinfection. That is, a case of yellow fever may be contracted from an environment after a considerable period of time from the last exposure of that environment to infection. I do not mean cases like those aboard the *Plymouth*, which were altogether exceptional, or the occasional hibernation of the fever in the United States. I mean cases like the following—I quote from only one season's note book:

"British ship *Avon*, in rock ballast, 22 in crew, all except 4 nonimmune, left Rio Janeiro April 20, 1900. All well in port and en route until the thirty-ninth day out, when entering Ship Island, a boy sickened with yellow fever and died; one other man, a quarantine employe who assisted in cleaning up the room where this boy was treated aboard ship, sickened 14 days after."

"British ship *Curlew*, from Rio, in rock ballast, crew mainly nonimmune. All well in port, en route, and on arrival. After cleaning ship, one man sickened with yellow fever, 64 days from Rio."

"British ship *Chippewa*, from Rio, rock ballast, 21 in crew, all save 3 men and the master nonimmune to yellow fever. All well in port, en route, and on arrival. After cleaning ship, one man sickened with yellow fever, 68 days from Rio."

None of these vessels made a port of call (except Pensacola) on the way up, and the date of leaving Rio was positively the last possible chance for any one of these vessels to acquire infection. We have, then, persistence of infection for not more than 39, 64, and 68 days.

Although the life history of Finlay's mosquito has not been worked out, the intervals of time here given exceed the life of any of the culicids whose life-history

is known and exceeds that given by Finlay for his. He states (verbal communication) that he has kept the female of his *Culex* alive, after feeding, only from 8 to 14 days; that the time from eggs laid in water to the time mosquito is from about 14 to 18 days. This agrees fairly well with what has been found for other culicids.

To explain cases like the above which, while not common, are by no means very exceptional on sailing vessels, in accordance with the theory of conveyance by the mosquito, one of three hypotheses must be adopted.

1. This mosquito has a far longer life than the other culicids, or than Finlay has been able to keep him in confinement.

Observe, there is no question of hibernation here, the route from Rio to Chandeleur in the spring and early summer is all under tropical conditions.

2. Unrecognized cases of yellow fever had occurred abroad en route.

3. That the immediate progeny of the infected mosquito coming aboard in Rio, are themselves infected and capable of transmitting the infection, as is the case with the host in the Texas fever of cattle.

The first is hardly reasonable; the time is so much in excess of the life of any other of the culicids. It is left, however, until the life history of this variety is better known.

The second seems to me also improbable. Still these cases are not common, and it is possible. Something too, I think, not much, must be allowed for the chance of a non-fatal case being concealed successfully from the quarantine officers.

The third hypothesis has, I think, not been in terms advanced by either Finlay or Reed, but is naturally implied (as a possibility at least) in the theory, and Dr. Finlay was engaged in investigating it when I left Cuba. He had secured eggs from a female which had been fed from yellow-fever patients, some laid on the surface of the water, and some on the side of the vessel above. These he intended developing and experimenting with the resulting mosquitoes to see if they would convey infection.

Even taking this third hypothesis, the time for the *Curlew* and *Chippewa* (and there are other cases) seems too long to be covered by the cycle from an infected mosquito to the life of his immediate progeny from eggs laid in water.

The eggs laid above the surface of the water, however, seem to be able to keep a long time (thirty days in Reed's case with eggs furnished by Finlay) and then hatched out when put in water. Taking this into consideration, even these long periods of time between cases, or after leaving infected ports to first cases, are not absolutely incompatible with the mosquito theory; although they are certainly not what we would expect therefrom.

Mosquitoes will not breed in bilge water (Finlay's verbal communication), and for them to so frequently deposit their eggs above water aboard ship, so that they will be wet, with fresh water, and come to maturity just when the vessel is cleaned, is decidedly improbable, less probable than the last hypothesis.

Fourth.—That the infection of yellow fever is conveyed by fabrics, clothing, and bedding especially, as fomites, is well nigh a universal belief.

With this the theory of Finlay and Reed is of course absolutely incompatible.

I have said that the conveyance by fabrics, directly

to men or by infecting an environment, is universally believed. Is it established?

There are many cases reported which are ascribed to this origin, and the writer has seen some which he believed thus due; those on the *Curlew* and *Avon* for example; and with the best revision he can give them, this seems for many the most, for a few the only, probable explanation, although it may not be the only explanation possible.

Yet it is fair to admit that his deduction from his own reports were influenced by his belief that yellow fever was habitually thus conveyed, and that he did not consider the possibility of its being conveyed by a host. He accepted this because it was universally accepted and because it was in accordance with the analogy of many other transmissible diseases. He used it as a proven theory to explain observations and did not make it as a necessary deduction from facts observed.

There is an experiment on a large scale which bears on this matter.

For a number of years (preceeding 1899), a large amount of baggage (used clothing) of passengers from Havana and Vera Cruz has been going to New York without disinfection. It is not possible but that much of this stuff came from infected houses and while most of it was clean, yet much of it was not. All of this baggage was opened at the Custom House at New York and handled in hotels there and at Saratoga, and no yellow fever is reported among the Customs Inspectors in New York.

The baggage going from the same ports to Spain for last 29 years is even more to be considered. Its amount has been enormous; much of it (from the class of people to whom it belongs) must have been foul. Some, the lesser part it is true, of this traffic goes to the Mediterranean ports of Spain—Valencia, Malaga and Barcelona, etc.—which at times, 1870 and before, have been infectible places, yet I think we have had no yellow fever reported in the Peninsula since the epidemic of 1870.

The facts cited above seem to me to have great negative weight and might be balanced against the positive evidence on this subject. It seems to the writer that the subject should be reopened, and that cases where this mode of conveyance is accused should be carefully scrutinized.

Fifth.—It is generally held by New Orleans physicians, that certain precautions of cleanliness will prevent the infection of his environment by a patient sick of yellow fever. These precautions take no account of the mosquito, and, save the general selection of an upper room for treatment, should not interfere with their access to the patient.

With this theory that of conveyance by the mosquito is inconsistent. There is some good evidence for this theory, yet it may be questioned if it is "proven." It is not universally accepted.

Sixth.—On the other hand the theory of conveyance by a mosquito is entirely consistent with the belief, very general but not universal, that yellow fever occasionally hibernates in the States north of the Gulf; as well as with the belief, less general, that it does not do so in the extreme southern portion of the United States, mosquitoes habitually hibernating in the first region and not doing so in the second.

There are several other postulates relative to the propagation of yellow fever which could be advanced;

but it seems advisable to set out only those which are well-known and universally, or very generally, accepted. Indeed the last three are outside of this pale—the last one especially.

SUPRARENAL CAPSULE—ITS USE IN RHINOLOGICAL OPERATIONS.

By CHARLES C. ROYCE, M.D.,

of Philadelphia, Pa.

Assistant in Rhinological Clinic, Jefferson Medical College Hospital.

THE literature is seemingly so full and complete concerning the employment of suprarenal capsule in rhinology, that one hesitates to further add to it; yet the results obtained by its use as herein indicated, while not altogether original, seem to justify recording, because the writer cannot recall having seen this method described elsewhere.

In all operative interference within the nose, it is desirable to have as small an amount of primary hemorrhage as possible, and certainly no secondary hemorrhage. The last result I have always obtained whenever this method was employed.

In doing a turbinectomy, the naris is completely filled with a tampon of cotton soaked in a 5% solution of cocain. This is retained within the naris some ten minutes, to be replaced by a fresh tampon similarly filled with a like cocain solution and retained another ten minutes.

Before placing this second cocain-soaked tampon within the naris, it is rolled in, and completely covered with dry suprarenal capsule, (Armour's).

When the second tampon is removed, a third is put in its place, soaked only with a 5% solution of cocain. This third tampon remains in the nose the same length of time as the others. In this way is complete and protracted anesthesia obtained.

Objections as to the amount of time incurred in this method will be raised, but the end surely justifies the means.

In hospital practice this method is obviously impracticable. A modification is to saturate a cotton tampon with a 5% cocain solution, then roll the same in dry suprarenal capsule, and tamponade for 15 minutes. The results are much more satisfactory than with the simple solution of cocain.

CASE 1.—Fred R., 25 years of age. Anesthesia was observed for upwards of 90 minutes. The case was only diagnosed as ethmoidal empyema. The anterior half of the middle turbinate was removed, four or five small polypi, and the anterior ethmoidal cells opened up.

CASE 2.—Edward O., 19 years of age. The patient's left naris was anesthetized with the three separate tampons. The inferior turbinate was completely removed. It was a great thick mass, twisted on itself posteriorly, like a conch shell, so that it was impossible to insert a catheter into the eustachian orifice by this route.

In neither case did the patient feel any pain nor was there any primary or secondary hemorrhage.

In Case 2 I wish to report an interesting sequel. While nothing other than a slight general hyperemia of the conjunctiva was observed at the end of the seance within 24 hours the patient complained of dizziness. The second day after the operation his vision was so imperfect that he was compelled to abandon his work. By the fourth day vision was normal.

In this relation it will be recalled that F. R. Packard¹ had a similar result after a turbinectomy, only his patient was temporarily blind.

In closing, it will not be amiss to allude to suprarenal capsule in the treatment of hay fever. I have yet to see one case benefited where it was used *internally*. The *dry* powder used in *insufflation* does remove lachrymation, coryza and the characteristic itching, or greatly modifies the same.

It is true that pure suprarenal capsule applied to the mucous membrane of the nose is likely to produce sneezing, and no little pain at first, but one can accustom oneself to these in view of the relief which supervenes.

To meet such conditions, Formula No. 1 is suggested :

R.—Cocain (pulv.) 2 grains.
Suprarenal capsule..... 3 drams.
Amyli, enough to make 1 ounce.
Mix.—Sig. Insufflate ad. lib.

In conjunction with Formula No. 1 during the autumn of 1900, I had most happy results with Formula No. 2, which appeared in *Medical Council*. Salicylate of soda was substituted for salophen. I am advised that this formula is now on the market in tablets.

Formula No. 2 :

R.—Heroin 1 grain.
Atropini sulph $\frac{1}{4}$ grain.
Caffeine cit 15 grains.
Sodii salicylas 75 grains.
Mix.—Ft. Cap. No. 15. Take 1 three times a day.

A CLAVICLE CRUTCH.*

By CARTER S. COLE, M.D.,
of New York.

In *Pediatrics*, December 1, 1899, Dr. Henry Ling Taylor illustrates "a new clavicle splint," which had, as he himself says, been invented by his father 20 years

A clavicle crutch.

before and used as a part of a spinal apparatus. He speaks of the case in which he used it as a clavicle splint for Dr. Powell, S.D., at the latter's request several years ago (about 1896). Since that time the constant employment of the Taylor splint has convinced me that one made distinctly for the purpose of supporting a

A clavicle crutch.

broken clavicle in the proper position, and at the same time furnishing a false clavicle, would relieve a great deal of the discomfort to the patient in the usual forms of dressing for fractures of that bone, and with it give as good results as we could get by more cumbersome methods. For more than a year I have used with great satisfaction the splint presented here to-night. The steel bands are held by a thumb-screw, thus enabling the easy change in distance between the two hard rubber supports. The latter are made to fit in the infra-clavicular space, and also to support the broken fragment of bone, and the simple adjustment of them by a thumb-screw allows us to change the angle of support as we may desire. The two circular pads, to rest upon either scapula, connected by a steel band may also be put further apart or closer together, as the case may demand. The broad straps passing from the hard rubber pads in front (over and under the shoulder) to the posterior leather pads, grasp and hold the shoulders with sufficient firmness to dispense with all forms of bandaging. A leather pad to fix the axilla, with a loop through which the lower strap can pass, would add solidity to the whole, but is not a necessary addition to the apparatus. The employment of this crutch in a single case will satisfactorily demonstrate its availability and superiority over the ordinary methods now employed in fractures of the clavicle.

A NEW TENACULUM.

By R. C. COFFEY, M.D.,
of Portland, Oregon.

BELOW is described an instrument, or set of instruments, which I have devised, and, I believe, is useful. It was intended to represent a tenaculum in idea, but acts on a principle different from any other I have

¹ "Reflex Disturbances of Nasal Origin," THE PHILADELPHIA MEDICAL JOURNAL, July 16, 1898.

* Presented to the Surgical Section of the New York Academy of Medicine, October 8, 1900.

hitherto seen demonstrated. Because of the manner in which the tenaculum is hidden when not in use, protruded when needed, and again drawn back into its receptacle when it has served its purpose, it has been called a "cat-claw" tenaculum. The mechanical principle by which the tenaculum is protruded and brought

CUT I.

into action is new, I believe, as applied to surgical instruments, and my instrument-maker believes it is new as applied in any kind of mechanics. At least we are safe in saying it is new as applied to the instrument represented. The accompanying cuts, I hope, will sufficiently illustrate its mechanical principles and uses. The instrument is composed of two principal parts, consisting of a metal tube represented in Fig. 1, and a steel rod which fits inside the tube, represented in Fig. 2. The tube and rod represented are adapted to either single, double, or quadruple tenacula. It will be observed, aside from being an ordinary straight tube, it has two rings for the index and middle fingers, a chamber on the bottom side for the reception of a ratchet which projects from the lower side of the rod, a spring with a catch which passes into the chamber and fits in the notches of the ratchet to prevent the rod being forced outward when traction is made on the tenaculum. At the lower end of the tube will be noticed openings or eyes through which the fangs are protruded. Inside the tube, just at the lower margin of each opening, is a small piece of metal, shown in the sectional view represented in Fig. 3, which serves to direct the point of the fang out through the opening and also to support it and acts as a fulcrum after it has been protruded. It will also be noted that on the spring are two arms which pass on either side of the tube, terminating in buttons by means of which the spring is thrown out of the notch in the ratchet by the index and middle fingers when the operator wishes to withdraw the fangs. The steel rod has at its upper end a ring for the thumb, on its lower side is the ratchet which receives the catch of the spring. Near the end of the rod are two hooks or fangs hinged on a rivet. One inch from the

end is a slot into which are fitted two other fangs when the quadruple tenaculum is needed. They are held in and hinged on to a screw rivet so they can easily be removed when not needed or replaced when needed. These fangs may be made any length necessary, but the curve must be great enough to comfortably fit the tube so the point will not pass the protrusion intended to direct them outward. Fig. 3, representing a sectional view of the instrument, shows the rod in the instrument with fangs just beginning to project. As the rod is pushed down by the thumb the fangs are forced out. If it is pushed still farther the points of the fang may be forced to a point almost touching the body of the instrument, making of it a very effective holding agent. The curve of the tenaculum thus formed is maintained by the ratchet and spring. Fig. 4 represents the instrument ready for use with the fangs still hidden. Fig. 5 represents the single cat-claw tenaculum in half curvature. Fig. 6 represents the quadruple cat-claw tenaculum. By removing the proximal fang, Fig. 6 would represent the double cat-claw tenaculum as shown in Fig. 2. The single and quadruple tenacula in Figs. 5 and 6 are shown in half curvature. By pushing the rod down one notch farther the points

are made to almost touch the staff of the instrument. Fig. 7 represents a cat-claw needle which might be used for passing ligatures in very inaccessible places. Fig. 8 represents a cat-claw knife with its edge protected by a second hook. This appliance may be used with advantage in removing sutures high up in the vagina or cervix. These two last appliances, however, are probably not important and may be fitted to the rod used for the single tenaculum.

Cut I illustrates one of the uses of the double tenaculum; namely, holding two membranes in position for a continuous suture. The tenaculum is shown in this case holding the peritoneum while a continuous

CUT II.

suture has been passed around it and drawn, the operator still continuing his suture to the upper end of the wound. After the suturing is completed the fangs of the tenaculum are withdrawn and the instrument slips out, leaving no opening. The double tenaculum is use-

ful also in closing rents or incisions in any of the hollow viscera as well as in applying continuous sutures in other parts of the body.

Cut II represents the use of the quadruple tenaculum in doing an operation for lacerated cervix. The distal fangs are pushed out into the sides of the uterine body while the proximal penetrate the anterior and posterior lips, holding the uterus down well, and fixing the two lips while the lacerated surfaces are properly denuded and later while the sutures are passed and tied. The staff acts as a guide so that the operator knows exactly how much of the mucous membrane is necessary to surround the instrument, thus making a cervix of exact and normal size. One side may be completed and the sutures tied before the other side is incised if the operator sees fit, and still he is assured that his result will be accurate. The sutures are drawn down tightly over the tube and tied firmly, assuring perfect approximation as well as an absolutely smooth canal. It has been my observation that the majority of operators do not get a smooth, even canal, and if a sound is passed it is hard to penetrate the body of the uterus because of the pockets which exist along the course of the newly made canal, due to some stitches being placed deeper than others.

The quadruple cat-claw tenaculum is also a very valuable aid in doing a vaginal hysterectomy. The instrument may be introduced well up into the body of the uterus and the fangs protruded. A suture is then passed around the cervix and tied tightly around the instrument, effectually closing the cervical canal and preventing any of the secretions from the uterine cavity infecting the field of operation. In this way the uterus is really forced up, down, from side to side, backward or forward, in fact in any direction for the convenience of the operator with just as perfect action as if the uterus were part of the instrument itself.

The single cat-claw tenaculum is especially useful where a tenaculum is needed in deep or close cavities which, under other circumstances make it difficult to remove the ordinary tenaculum on account of its tendency to reinsert itself into everything with which it comes in contact. For instance, it is well adapted for holding the uterus while stitches are being passed in the operation for ventrosuspension of the uterus; for the sutures may be even partially tied around the instrument; yet it is withdrawn without complication. No amount of sutures, omentum, gauze, or intestines will entangle this tenaculum; for while it is in action the point may be turned in to such an extent that it will not catch the surrounding parts and is still easily withdrawn along the inside of the tube. The instrument is manufactured by Charles Truax, Greene and Company, of Chicago.

While one instrument, the quadruple tenaculum, may be used as a double tenaculum by removing the two proximal fangs, or as a single tenaculum by removing all the fangs and putting in a single tenaculum with a wide base, it would be more convenient to have three separate instruments, a single tenaculum, a double tenaculum, and a quadruple tenaculum; for we frequently need at the same operation the quadruple tenaculum for a cervix operation, a single tenaculum for a ventrosuspension, and a double tenaculum in closing the abdominal wall.

Diphtheria Antitoxin as a Treatment for Pneumonia.—At a recent meeting of the Medical Society of the Paris Hospitals, Dr. Talamon (*Journal des Praticiens*, March 9, 1901, No. 10) reported observations made upon **50 cases of pneumonia**, ranging in age from 5 to 75 years, **treated by enormous injections of antidiphtheritic serum.** Complications due to the serum, cutaneous and articular, occurred in but 5 cases, one of whom, an old woman, 72 years old, died. No cardiac symptoms were noticed, though 6 patients were between 60 and 75 years of age. All cases showed albuminuria while the fever lasted. Talamon believes that diphtheria antitoxin is only contraindicated in cases with liver or kidney disease. Under 50, he advises 2 or 3 injections of 20 ccm; 4 or 5, over 50. In extreme cases, 6 or 7 injections may be necessary. This should be decided by the temperature; if it rises again, the injections must be continued. The sooner this treatment is begun, the less will be the number of injections necessary. In very grave cases, the injections should be given twice daily. By the use of diphtheria antitoxin, Talamon thinks the duration of the pneumonia is diminished; the chance of complications occurring is less; and the mortality is lowered 10%. Though a man with Bright's disease or diabetes often cannot recover from pneumonia, Talamon's results, 25 cases, treated before the fifth day, with one death (at 72 years), predict a bright outlook for this new treatment. Let us hope that further experiments will be undertaken. Heubner has already shown that diphtheria-antitoxin is harmless, by the method he employs at the Charité Hospital in Berlin, where every child in the ward receives an injection of antidiphtheritic serum once a month. [M.O.]

Suppurative Chickenpox, and Secondary Suppurations in the Course of Chickenpox.—Lucien Désandré (*Gaz. Heb. de Méd. et de Chirurg.*, February 24, 1901, 48me Année, No. 16) says the vesicle of **chickenpox** does not normally suppurate, although in certain instances pus is met with in the lesions of the disease. In the **suppurative form** the vesicles usually evolve normally, but at the end of a day or two they increase in volume, become flattened and filled with a yellowish or greenish pus. Sometimes they become umbilicated and surrounded by an inflammatory areola. This suppuration lasts several days, then the vesicle ruptures or desiccates slowly. In these conditions the crust is much thicker than that met with in ordinary chickenpox and is also much more adherent. Furthermore, after it is shed a depressed cicatrix, analogous to that met with in smallpox, remains. The duration of the evolution of a suppurating vesicle may be more than 3 weeks, whilst the normal lesions of chickenpox only persist for about 15 days. The purulent transformation of the contents of the vesicle is often accompanied by a true fever of suppuration, as in smallpox. Among the complications of suppurating chickenpox, general infection, gangrene, and nephritis are the most common. The bacteriology of simple chickenpox is little known; but in suppurating chickenpox the constant presence of the *Staphylococcus pyogenes* has been shown in some instances associated with the streptococcus. The pus of these lesions contains a number of polymorphonuclear leukocytes. On the other hand, pus of smallpox and the fluid of simple chickenpox contain mononuclear leukocytes in greatest proportion. The differential diagnosis between smallpox and suppurative chickenpox is based particularly upon the induration of the skin which accompanies the pustule of the former disease, and also on the fact that in suppurative chickenpox the pustules are more elongated and larger than those of smallpox. The suppuration of chickenpox vesicles has been explained either by general causes, such as debility or cachectic states in patients or by local causes depending upon a former condition of the skin. But suppurative chickenpox is often epidemic and contagious, and in order to explain such cases it would seem as though the patient had been inoculated by the virus of chickenpox and the ordinary organisms of suppuration at the same time. In the course of chickenpox secondary suppuration, such as furuncles, abscesses, and general infection through the lymph channels have been noticed. Furthermore, multiple abscesses in the skin, in the subcutaneous tissue, and in the joints and viscera have also been recorded as complications or as sequelae of chickenpox. In such cases the infection is spread by the blood-paths. [J.M.S.]

The Cause of Vaccinia and Variola.—There has been no lack of reports concerning the cause of vaccinia, but in spite of the claims of a number of investigators that the cause is a bacterial one, it must be said that the protozoa described years ago by Guarneri, Pfeiffer, and others, have, perhaps, the greatest number of points in their favor as the actual cause of the affection. The active interest awakened by the earlier reports concerning these organisms has quieted down, because of the years that have passed without any addition to our knowledge concerning them. New interest has, however, been added to these organisms by the recent report of Funck (*Deutsch Med. Woch.*, Feb. 28, 1901), who states very positively that they are the cause of vaccinia; indeed, the very positiveness of his statements is likely to arouse a certain degree of skepticism. The results he has obtained are, however, of value, and a more complete report will be awaited with interest. The organisms described are apparently actually those written of nearly fifteen years ago by the authors mentioned, though Funck gives further details concerning their morphology, and contributes some additional points concerning the method of demonstrating and studying them. The chief point upon which he bases his statement that he has demonstrated their etiological relation to vaccinia, is his observation that while the individual organisms are small and range from 1 to 3 microns in diameter, large cyst-like bodies, which have a diameter as great as 25 microns, were often to be seen, and these were, by careful examination, shown to be filled with spores. A culture, in a bacteriological sense, of these protozoa, cannot be made, but Funck states that he took so-called sterile lymph which contained only a small number of the protozoa, and was therefore much more readily examined than the contents of pustules, smeared this lymph over the surface of an ordinary agar plate, and place it in the thermostat for 24 hours. Examination at the end of this time by means of a low power of the microscope enabled him to pick out the large spore-containing cysts with readiness, and by means of a fine platinum needle he isolated these cysts, and used them for purposes of injection. The

injections produced what he believed was a typical vaccinia, and after suffering from this disease, the animals were immune to inoculation directly from vaccinia pustules. He states that the protozoa can, by his more complete and accurate methods of examination, be found in all vaccinia pustules and in the immediately surrounding tissues, and he considers that their constant presence in the disease, together with the fact that injection of the isolated sporoblasts, produces typical vaccinia, demonstrates conclusively that they are the cause of vaccinia. He was also able to find protozoa of identical appearance in a case of variola, and concludes from this that the two diseases are due to the same cause, differences in the virulence of the protozoa being the cause of the variations in the results of infections produced by them. It has been quite thoroughly established that cowpox is actually a modified form of smallpox, and one cannot reasonably object to Funck's conclusion that variola and vaccinia are due to the same cause. It may, however, be properly stated that the investigations reported do not fully support the statements made by Funck. There are too many possibilities of contamination in the method used to exclude the possibility that some other infection was introduced at the same time with the sporoblasts. The results described, however, do approach fairly closely to a demonstration that these protozoa are the cause of vaccinia, and, with our present knowledge, it seems highly probable that if they are the cause of vaccinia, their virulence becoming increased, they may also be the cause of variola. This report, taken in conjunction with the older reports concerning the same organisms, constitutes the most interesting contribution yet made to the nature of the specific cause of these two affections.

Pregnancy Subsequent to Double Salpingo-Oophorectomy.—The occasional report of a gestation occurring in a woman from whom both tubes and ovaries had been removed at a previous operation, attracts a passing attention and temporarily awakens speculation as to the cause of such a remarkable phenomenon. The recent interesting paper of Morris in the *Boston Medical and Surgical Journal* of

January 24th, brings the subject again to the front. Morris reports an instance of this peculiar accident, and culls from the literature a number of other reported cases, the most remarkable of which is that of a German surgeon, the pregnancy resulting in a tube implanted in the vaginal vault after hysterectomy. Such cases sooner or later find their places among the curiosities of medicine and surgery. It is not at all improbable that in some such manner first arose the supposition as to the existence of a third ovary, it being at once admitted that gestation could not occur without the presence of ovarian tissue from which a Graffian follicle had been developed and an ovum discharged.

In a certain small percentage of female pelves that have been examined post mortem undoubted instances of a third ovary have been noted. A further search must be made, however, in order to arrive at a definite conclusion as to the cause of these curious, and at first sight almost impossible, pregnancies occurring in women in whom no such additional ovary could be discovered. Excluding the existence of a third ovary, two other factors must be taken into consideration, namely, the retention of a portion of healthy ovarian tissue after excision of both organs, and a re-patency of the Fallopian tubes after ligation. The case of tubal pregnancy already referred to occurred in a patient in whom the uterine appendages were retained and carried down to the vaginal vault, where their function not being interfered with, gestation was quite possible.

There has of recent years occurred a marked reaction in the technique of abdominal section, and it is now recognized that whenever possible a portion of ovarian tissue should be retained in the pelvic cavity. There thereby results an arrest of the unpleasant phenomena of the induced menopause, in consequence of which the patient is more comfortable and the natural phenomena of the period of sexual activity continue. This retention of normal tissue is, of course, a *sine qua non* for the occurrence of a subsequent pregnancy, granted a third ovary does not exist in the pelvic cavity. It is not necessary that the ovarian fragment occupy its normal site; a piece of cortical tissue transplanted to the uterine fundus or implanted in the broad ligament can just as surely functionate. In order for the discharged ovum to find access to the fertilizing element, however, a second essential element in the process must be present, namely, a patent condition of the Fallopian tube. In fact, according to Frankel, the difficulty lies not in securing firm ligation of the oviduct, but in preventing a subsequent restoration of the lumen of the stump. Not only has every variety of ligature employed by him to secure accurate apposition of the walls of the tube failed to

accomplish its purpose, but even after resection of a portion of a tube and the use of the thermocautery the tube has again become patent. Only after total exsection of the oviduct from the uterine fundus with closure of the wound by a peritoneal flap did he succeed in obliterating permanently the opening into the pelvic cavity.

When the foregoing fact is borne in mind, and it is also noted that in a very large number of abdominal sections, as now performed, a fragment of ovarian tissue is intentionally retained, the wonder is not that subsequent pregnancy should occur, but that it should occur so infrequently. This possibility of retained fecundity opens up a new question in the agitated subject of conservative gynecological surgery in those cases in which offspring may be desired.

It will be seen, therefore, from the foregoing resume, that three elements may be concerned in the development of the obstetric paradox—gestation subsequent to double salpingo-oophorectomy—namely, the possible presence of a third ovary, the retention of a fragment of functioning ovarian tissue, and a patency of one or both Fallopian tubes, the latter two facts being absolutely essential to the occurrence.

The Conference on Tuberculosis in Canada.—

The *Montreal Medical Journal* sees much to hope for in the fact that Canada has now a Tuberculosis Conference of its own. We congratulate the *Journal* and also the Dominion in view of this progressive step. Lord Minton, the Governor General, gave his full support in helping forward the crusade against tuberculosis by calling the recent Conference at Ottawa and allowing himself to be termed its "patron". The *Montreal Medical Journal* sees in such a permanent Association, working satisfactorily to one end, the promise of much better results than can be obtained by sporadic attempts to obtain legislation. Its publications, as the *Journal* says, can reach all sorts and conditions of men from the school room upwards. It is an important move on the part of the Association that it established its headquarters at Ottawa, where, as the *Journal* says, it can not only make its needs felt by the Government, but can also obtain upon its Council prominent members of the Dominion Parliament.

The addresses delivered at the recent conference in Ottawa were not as a rule strictly scientific, but the object of the articles was evidently to bring forward the general subject of tuberculosis in a way that could readily be understood by the general public. Papers of this kind, we are convinced, are highly important in all such Conferences on tuberculosis. In other words, these national associations, which are now getting to be the fashion, should not

apply themselves too strictly to technical papers, but should devote part of their time to an endeavor to educate the people on this subject. We are to be congratulated in this country that there has been a large awakening of public interest, in some parts at least, on the subject of tuberculosis. We know that in some States an active campaign has been undertaken, and that even the pulpit and the lecture room have been used to disseminate knowledge. This was done so successfully in the State of Maine, which is near to Canada, that the Health Officer of the State, in his recent annual report, was able to claim that the lower rate of mortality from tuberculosis was due in part, if not wholly, to such instrumentalities. It seems probable that the Twentieth Century will be especially identified in the history of medicine with the great advances that are to be made in the field of public and preventive medicine. Tuberculosis, leprosy, plague, yellow fever, malaria, and cholera are some of the most conspicuous diseases that call for widespread national treatment and State control.

The Antitoxic Action of Bile.—*The Literary Digest*, quoting from several French scientific journals, gives some curious information on this subject. The natives of Bengal have believed for centuries, it seems, that the liver is a reliable antidote for hydrophobia, and they do not "some of the hair," but some of the liver, "of the dog that bit you." We have it on the authority quoted, that when a mad dog bites a man in India, the animal is killed and his "palpitating liver" is removed, cut into pieces and fed to the patient. This is said to be a sure cure. To come nearer home, in the interior of France the peasants have used bile as a remedy for the viper's bite from time immemorial. This empirical knowledge seems, according to Neufeld, to be about to acquire a scientific basis. This observer publishes a series of experiments in a recent number of the *Zeitschrift für Hygiene*, which show the destructive action of the bile on certain microbes. The action of the rabbit's bile is very disastrous to pneumococci. Under its influence these microbes diminish rapidly, their contours become less and less clear, and they finally disappear in the liquid. These bacteriolytic properties of bile exist in the healthy as well as in the sick rabbit, and the bile can dissolve three hundred times its volume of a culture of pneumococci. The bile of man, as well as of the monkey, the guineapig, the dog and the cat, has this faculty, but not so actively as that of the rabbit. It is claimed that a subcutaneous injection of bile in which pneumococci have been dissolved, makes a guineapig immune to infection. The serum of the rabbit's blood has none of the bacteriolytic action of the bile. On the other hand, the rabbit's bile

exerts no such action on the cholera bacillus, the bacillus of Eberth, or the diphtheria bacillus. But it seems to have an action on the virus of hydrophobia. The active ingredient of the bile is probably the cholic acid, a non-nitrogenized substance formed in the hepatic cells.

Traumatism of the Pharyngeal and Laryngeal Mucous Membranes.—Among the many interesting features of the investigations which have been carried on by Crile, of Cleveland, for the past few years, are those observations upon the inhibitory effect upon the respiratory and circulatory apparatus attending traumatism of the pharyngeal and laryngeal mucous membrane. In his studies of the pathogenesis of shock, Crile has paid particular attention to the effect of trauma in different regions and tissues upon the blood pressure, and of particular interest were the results attending traumatism inflicted upon the mucous membrane of the larynx and pharynx. It was found that the subjection of the mucosa of the larynx or pharynx to any insult always had an inhibitory effect upon the respiratory and sometimes upon the cardiac apparatus, the upper or superior portion of the larynx being particularly sensitive. These inhibitory messages were proven to have been transmitted through the superior laryngeal nerve, as upon section of this nerve these inhibitory phenomena were not exhibited. The sudden deaths attending the introduction of the intubation or the tracheotomy tube may, according to Crile, be accounted for in this way. Many a surgeon can recall one or more occasions in his experience when sudden death from respiratory failure, not from asphyxia, immediately followed the introduction of the tube. In some cases the anesthetic was held at fault, in others it was said that the tube had become plugged with a piece of membrane, and in other ways attempts were made to account for this sudden and fatal complication. Just at the time in which relief to the already partially asphyxiated subject is at hand, sudden death robs the surgeon of a recovery that seemed assured. That these deaths are not due to asphyxia will be admitted if one but stops to think of the clinical picture, noting particularly the almost instantaneous interruption of the respiratory act in sudden death from respiratory failure, which contrasts strongly with the increased respiratory efforts, lasting several minutes, by which the subject with asphyxia attempts to overcome the effects of obstruction to the ingress of air. If one could anesthetize the mucous membrane of larynx or pharynx before the introduction of the intubation or tracheotomy tube, or in laryngectomies before attacking the larynx itself, there is reason to believe that this complication could be averted. To this

end Crile has introduced into his technique of this operation the complete anesthetization, by the infiltration method, of the tissues of the larynx.

The results of investigations upon the pharynx would seem to condemn the practice of vigorously swabbing out the fauces during ether narcosis. This is a practice which no doubt is justified in certain instances, as, for example, when the collection of mucus is large enough to embarrass respiration. We are inclined to believe, however, from our observations, that it is resorted to much more frequently than necessary, and in such instances it should be regarded as a mischievous practice. If, as Crile reports, vigorous traction of the tongue likewise produces reflex inhibition of the respiratory function, some caution should be observed in the restoration of patients by the Laborde method—the rhythmical traction of the tongue. So, too, in those cases in which, in its relaxed state, the tongue falls back into the pharynx, the anesthetizer should be mindful of this possible inhibitory effect and should not apply the tongue forceps needlessly, nor make too vigorous traction upon that organ.

Experimental Hepatic Cirrhosis.—In few varieties of hepatic cirrhosis is the etiological relationship more clearly and definitely established than in that form due to the action of bile on the organ, in the course of obstructive jaundice.

Dr. Vaughn Harley and Dr. Wakelin Barratt have recently published a very valuable contribution on "The experimental production of hepatic cirrhosis" (*Journal of Pathology and Bacteriology*, February, 1901). These observers, after careful and painstaking experimental researches made upon rabbits and dogs (on the effects that are produced by the ligation of a biliary duct) have deduced several important conclusions. They demonstrated that bile continued to be secreted in the area affected by the ligation of the biliary duct. It appears that the bile escapes from the fine biliary capillaries by osmosis. The constant presence of bile outside of the biliary passages causes irritation, and interlobular fibroid tissue is produced.

The increase in the interlobular bile ducts, which the authors observed, they believe is due to overdistention of these vessels, thereby causing elongation and tortuosity. After a careful study of their sections, they do not feel justified in sustaining the view that new bile ducts are formed.

The atrophy of the liver cells, occurring in the course of this form of obstructive biliary cirrhosis, they show, is most probably not due to the contraction of the newly-formed fibrous tissue, but to the toxic action of the bile. This atrophy primarily, and almost exclusively, involves the peripheral cells of the liver lobule.

Different animals of the same species, experimented upon, reacted with a considerable degree of variation, although the operative procedures were identical.

The Classification of Disease.—That medicine is an art and not a science, is such a trite saying that it seems almost useless to repeat it. And yet to read a modern text-book of medicine, particularly that department which is designated by the continentals as "internal pathology," brings the matter to our attention with such force, that it is worth while to inquire why physicians, of all men, should be so unscientific in the broader field of their work. That is to say, in that department in which medicine is considered as a whole, and not as the mere practical application of a more or less imperfect knowledge of therapeutics to some pathological symptom or morbid condition. What we mean by speaking of the manifestly unscientific nature of the whole subject is illustrated by the classification of disease. Now we take it that the following definitions, taken from the *Standard Dictionary*, are fair representations of the modern conception of the significance of the word. (1) "Disease is any departure from, failure in, or perversion of, normal physiological action in the material constitution or functional integrity of the living organism. (2) The morbid condition resulting from such disturbance or failure of physiological functions." But medical men have employed the word in at least three different senses, none of which are covered by this definition. They are: (1) "Disease is a morbid condition resulting from some particular pathogenic agent. (2) It is the morbid condition resulting from the involvement in some definite manner, of a certain tissue, or group of tissues, constituting an organ, (3) It is a collection of symptoms commonly occurring together, and apparently bearing some mutual relation to one another." It will be seen from these three definitions that the first involves the etiology; the second, the pathology, and the third the symptomatology. Perhaps we can make this a little clearer by illustration. For example, epidemic cerebro-spinal meningitis is a special form of disease due to the invasion of the organism by the diplococcus intracellularis of Weichselbaum. This usually develops its chief activity in the pia-arachnoid of the brain and spinal cord, and is therefore a disease according to the first definition. Acute cerebro-spinal leptomeningitis is an acute inflammatory process affecting the pia-arachnoid of the brain and cord, and may be produced by a great variety of microorganisms, besides the meningococcus. It is a disease according to the second definition. Finally we may have a condition characterized by certain symptoms, such as headache, photophobia, and

retraction of the head, from which the patient may recover or die, and absolutely no pathologic changes can be discovered in the central nervous system. This is sometimes spoken of as meningism, and would be a disease whose sole characteristic, according to our present knowledge, would be an occurrence together of a certain group of symptoms. Or, to take a more familiar example, we might speak of migraine, which has, as far as we know, no anatomical or definite etiological basis. Now, unfortunately in our text-books on medicine, the authors do not content themselves with the adoption of a single definition of this nature, classifying all disease according to it, but they jumble all three together in a most heterogeneous and unsatisfactory fashion. The great majority believe that they approximate accuracy if they give an etiological classification, and they proceed to do this as far as possible. Nevertheless, they describe croupous pneumonia in the "diseases of the lungs"; they put together all the forms of acute leptomeningitis, excepting the epidemic form, and place them in "diseases of the nervous system"; they put the epidemic form, very properly, it is true, according to their adopted system, in the "infectious diseases." They do not discriminate between the various forms of pericarditis, appendicitis, and pleuritis, although any one of these diseases may be due to a great variety of specific germs. They do not even attempt to carry out their own principles. A section is devoted to diseases of the kidneys; one to diseases of the lungs; although both of these organs may be affected by tuberculosis, and these two forms should properly be grouped together. The different types of cirrhosis of the liver are discussed as pathological entities, not etiological, and the functional diseases of various kinds are grouped, often without reference to the organ affected, or even to the characteristic symptoms, as a rule in the section on nervous diseases, where many of them certainly do not belong. Of course, it will be urged that this unscientific, and to a certain extent, unsatisfactory method of classification is caused by the limitation of our knowledge. That we are not sufficiently acquainted with the etiology of many diseases; that it is necessary for convenience to group the various affections of the different organs together, and that the diseases characterized only by symptom groups, are usually instances of disturbed nervous energy, or at least disturbance of certain of the ductless glands whose functions are not clearly understood, may be granted, and yet, if it is, it would seem more rational either to discard the etiological factor as far as possible, or to adopt it to the fullest possible extent, and to group the other diseases according to pathological processes, rather than according to organs.

It is our firm conviction that the confusion of the other prevailing method is rather a matter of custom, than of the actual superiority or necessity. Unfortunately, at the present day men take a broad, comprehensive view of medicine as a whole, but each is devoting himself to some little domain, or to the exposition of some particular fad, and the exposition of the mutual relations of the different parts suffers.

The Social Evil in New York Tenement Houses.

— The Committee of Fifteen, which is now trying in a practical way to bring about some reforms of vice in New York city, has taken up the subject of prostitution in the tenement houses of that city. In a letter recently written to Governor Odell, it says that the existing condition of affairs is not only deplorable, but intolerable. It seems that the practice of prostitution has become very prevalent in these over-crowded tenement houses. The Committee draws attention to the fact that the most shocking feature of this evil is the prostitution of young children. Women of ill-repute find shelter in these houses, where they are apparently exempt from police surveillance, and here they sow the seeds both of vice and of the venereal diseases in a promiscuous population, both of young and old of both sexes. The social evil must be attacked and exterminated in the tenement houses before any permanent control can be gained over it in that city. The Committee endorsed the legislation proposed by the Tenement House Commission. We learn from the *Medical Record* that the penalty for allowing any part of a tenement house to be used for immoral purposes is a fine of one thousand dollars, which shall be a lien on the property. This makes the owners of such houses, and not the wretched women who pursue their avocation in them, directly responsible for suppressing this vice.

The Symptoms and Treatment of Mercurial Sore-Throat.

—A. I. Liants (*Klinicheskoye Zhurnal*, December 1900) believes that the mercurial affection is as a rule circumscribed and limited to certain areas. Frequently the inflammation is bilateral. In the majority of cases only the pharynx is affected, the mucous membrane of the gums, cheeks and tongue remaining healthy. Mercurial angina is accompanied by pain on deglutition which is at times severe and transmitted to the ear and temples, and also painful enlargement of the submaxillary glands. Acute onset with diffuse redness of the mucous membrane of the throat, dizziness, headache, nausea and vomiting and elevation of the temperature is rarely observed. The necrosis of the epithelium produces indentations which are covered by a grayish-white substance composed mainly of epithelial debris. These erosions are superficial although they have a tendency to extend to the deeper structures. To prevent mercurial inflammations, the patients taking mercury should wash their mouth with some antiseptic both before and after each dose. The mercurial angina is best treated with peroxide of hydrogen, while the ulcerations should be treated by applications of nitrate of silver, chromic acid and glycerin-emulsion of iodoform. [A. R.]

Correspondence.

THE OXYTOXIC ACTION OF SPINAL ANESTHESIA

BY S. MARX, M. D.

of New York City.

To the Editor of "The Philadelphia Medical Journal."

Sir:—In your issue of last week, date March 23. I note your leader entitled "The Oxytoxic Action of Spinal Anaesthesia," I read your comments with considerable surprise. Since they are at variance with the views held by men well experienced with this form of anaesthesia. This differing in opinion is the right and privilege of all free men; it should always be encouraged in order to fathom that which we all are after; scientific truth. This is well exemplified in your editorial so far as the general run of statements go. So far, so good, but when further on I note the tone of some of the sentiments expressed I certainly wish to call an emphatic halt. Spinal cocaineization will never supplant cerebral anaesthesia, because it will ever have an extremely limited field. What this limitation is does not enter into consideration. I feel satisfied that the gentleman who wrote this editorial is a capable and careful writer and that the errors committed in the following lines are not those of a deliberate misquotation but errors of inadvertence. "The very decided mortality rate attendant upon cocaine injections, etc." Now, Mr. Editor, in a spirit of fairness, of honesty, of equity, will you kindly state in your next issue upon what evidence you base your remarks. More than likely you were influenced by the remarks made in the New York Academy of Medicine some months ago. Are you aware of the fact that the very men who alarmed the whole community by their wholesale misrepresentations of facts were men with little or no experience in this method at all? I can tell your readers something which has never appeared in print before; why, I do not know, though it occurred in open meeting before the Greater New York Medical Association. The gentleman who was supposed to be responsible for the following damning statement absolutely denied having said so and had excused those men for having twisted words in his own mouth. His supposed words were to the effect that a certain French operator had reported that out of 100 punctures there were only 17 successes and 5 deaths. These remarks were made before the most prominent society of this country. They were written and copied and sent broadcast, north, east, south and west. When these same men were proven wrong; that their quotations were decidedly fakey, when the medical journals and their reporters who were present on the two occasions knew well the same, did any of them have the honesty of their convictions and state in writing in such large letters that the whole world could read, that they wished to correct a wrong? If it has appeared, I for one have not seen it. In the many of the hundreds of cases of spinal anaesthesia reported, Tuffier is the only one who reports a fatal case, but the autopsy with its heart and lung lesions makes me rather a doubting Thomas as to the real cause of death. There have been rumors of deaths in various parts of the country but on investigation they all as quickly disappear as the snow does before the spring-time sun. Now, as to another erroneous quotation and a personal one: "Thus Marx, of New York, in a series of cases thus treated, was compelled to hasten delivery in 16 instances by the application of forceps." This statement I never made and I

call for proofs. Nearly all of my cases were operative ones or were made so because of the presence of an ever inquiring audience. All my cases were delivered before an audience of physicians, and while they were willing to remain for a short time to watch the progress of labor they were most unwilling to camp out over night in a pauper hospital to watch a tedious labor case, no matter what the inducement was, short of a pecuniary one and that neither the commissioners nor I were willing to stand for. Enough to my own satisfaction was the proof that most of the cases would have delivered themselves normally even as they would have done under ordinary conditions. Only in one case did I notice secondary weak pains, but since this occurs quite often during the parturient act I could not at that time nor can I to-day hold the cocaine responsible. Neither have I, on the other hand, ever noticed an oxytoxic action after spinal anaesthesia. I have performed all the obstetric operations under its influence. They are all readily done but not with quite as much ease as under chloroform. There was never a greater predisposition to bleed. Personally, I believe that the contractions are not influenced one way or the other, neither made stronger nor weaker. Now, Mr. Editor, this letter is written in a spirit of the frankest criticism, and I hope you will receive it in such a spirit and grant me a little space in which to ventilate my thoughts.

[Reference to the editorial in question will show that the writer, after commenting on Prof. Doleris' suggestion that spinal injections of cocaine should be used to hasten sluggish uterine contractions, felt impelled to take the conservative course and refrain from speedily adopting what he felt was a method of treatment not yet demonstrated to be free from danger. The experiments of Bier and Seldowitsch indicate the possibility of serious results following the cocaine injections. The conclusions of the writer are merely in accord with those of other students of surgery, notably Keen and Da Costa, who in the last volume of the American Year-Book of Medicine and Surgery, remark that "the real value of the method is uncertain," and again the "view that absorption of cocaine produces the unpleasant after-effects seems to receive confirmation from the fact that the injection of normal salt-solution into the subarachnoid space is not followed by giddiness, vomiting, or headache. "As to the statement concerning the statistics of Prof. Marx, we would kindly refer to an editorial in The Lancet of March 2, 1901. When ample statistics are at hand to prove conclusively the desirability and safety of lumbar puncture for inertia or other conditions, the writer will prove that he is

"Not the first by whom the new is tried
Nor yet the last to lay the old aside."

Fixation Abscesses.—About ten years ago, Professor Fochier proposed the production of abscesses by the subcutaneous injection of an irritant, as a treatment for grave septicemia. Arnozan (*Journal de Medecine de Bordeaux*, March 17, 1901, No. II.) reports eight cases in which he followed this plan. They were cases of pneumonia, typhoid fever, phthisis, and bronchitis. Four of them recovered, two improved greatly, and two died. Turpentine was used as the irritant, and those who died both had nephritis. Great care should be taken to avoid secondary infection, as the fixation abscess is perfectly sterile. Arnozan believes that the polynuclear leukocytes, which accumulate on reaching the abscess, there give up the microbes which they have absorbed from the blood. Were it not for this means of exit, the polynuclear leukocytes, on reaching a hematopoietic organ, might become the cause of autointoxication. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

College of Physicians.—At a meeting of April 3, Dr. James Tyson read A Memorial of the late Dr. William Pepper. In it he reviewed the work of that great man as a physician, teacher, organizer, founder and philanthropist.

Dr. S. Osmond Goldan, of New York, read a paper on Nitrous Oxide and Oxygen as a Surgical Anesthetic; Description of a new apparatus for administering these gases, report of 100 operations, the narcosis lasting half an hour upward; remarks regarding the use of nitrous oxide as a preliminary to ether in general anesthesia. Nitrous oxide and oxygen was stated to be a safe anesthetic, to which there is no contraindication. Nitrous oxide is said to cause anesthesia by asphyxiation but by the fact that it will produce anesthesia when oxygen is given in conjunction with it. When more than 30 per cent. of oxygen is used, anesthesia cannot be obtained. In the use of this anesthetic there must be given the full attention of the administrator. The patient should be placed on the operating table first. The nitrous oxide is first begun, about 6 breaths of it being given, then oxygen. Anesthesia is induced in from 60 to 120 seconds. The apparatus is a 7-shaped tube with a cut off to regulate the amount of oxygen given. The 100 cases reported consisted of hysterectomies, nephrectomies, amputation of the breast, etc. The time varied from one-half hour to 2 hours and 40 minutes. The pulse is raised very little above the normal if any, and respirations remain about normal. Nausea, vomiting and headache follow in some cases, the latter not being severe. Alcohols are difficult to get under. The large quantities of gas used make it the most expensive method in use. Nitrous oxide is also of value as a preliminary to the use of ether. Dr. Thomas R. Brown, of Baltimore, stated that he had used nitrous oxide as a preliminary to ether anesthesia in 15 or 20 cases and that his faith in the method increased with the number of cases in which it was used. Dr. John G. Clark said that with this method a specialist was needed to give the anesthetic. With the present arrangement regarding hospitals it was not practicable here. In the London hospitals where professional anesthetizers are hired, it would probably work very well. Dr. Keen stated that Dr. Goldan had anesthetized patients in his clinic that day and that he was well pleased with the results attained, very little cyanosis being caused. Dr. Goldan said that hospital internes should be arranged as junior and senior so that one experienced man would be anesthetizing and the new man simply watching and helping him for the first months of his service. He believes that all minor operations should be done under nitrous oxide and oxygen anesthesia. If it will not answer then another anesthetic can be used.

A paper by Dr. Orville Horwits entitled **Hydrocele—Its Treatment; Summary of 338 Operations; Description of a new method suggested by Doyen for the radical cure of Hydrocele of the Tunica Vaginalis**, was read by Title.

Physician Killed by an Insane Patient.—Dr. R. Erskine Johnston, of the Medical Staff of the State Hospital for the Insane, at Danville, was killed by a patient in that institution. Dr. Johnston, who entered the room of the patient in order to take his temperature, was warned by the insane man to keep away from the bed. The doctor called an attendant to assist him, the latter holding one hand of the patient, while the physician taking the other, seated himself at the side of the bed. Disengaging his right hand, the patient struck Dr. Johnston several blows. The doctor staggered out of the room, fell over and expired. Where each one of the blows took effect on the doctor's body a puncture was found as if produced by a slender instrument. The matter is being thoroughly investigated.

Presentation of Dr. Keen's Portrait.—The students of Jefferson Medical College presented to that institution on Thursday evening, April 4, a portrait of their Professor of Surgery, Dr. W. W. Keen. The exercises were held in the amphitheatre of the Jefferson

Medical College Hospital, which was beautifully decorated with palms and college colors. The presentation speech on behalf of the students was made by Prof. J. Chalmers De Costa, with his usual eloquence. The address of acceptance was made by William Potter, President of the Board of Trustees, who spoke of the fidelity of the students to their alma mater. The portrait shows Dr. Keen wearing the robes of a Fellow of the Royal College of Surgeons.

Vital Statistics of Philadelphia for the week ending April 6, 1901:

Total mortality	490	Cases.	Deaths.
Inflammation of appendix 7, bladder 2, brain 13, bronchi 7, kidneys 14, larynx 2, lungs 73, pericardium 1, peritoneum 6, pleura 3, stomach and bowels 20	148		
Inanition 18, marasmus 13, debility 6, Tuberculosis of the lungs	37		
Apoplexy 23, paralysis 3	66		
Heart-disease of 31, fatty degeneration of 1, neuralgia of 5	26		
Uremia 7, diabetes 2, Bright's disease 9, Carcinoma of face 1, breast 2, stomach 3, uterus 2, liver 1, pelvis 1, tongue 1 ..	37		
Convulsions 19, convulsions, puerperal 3 Diphtheria,	18		
Brain abscess of 2, congestion of 3, softening of 2	11		
Typhoid fever	22		
Old age	72		
Cyanosis	12		
Scarlet fever	7		
Influenza 1, aneurism aorta 1, alcoholism 1, asthma 1, anaemia 1, atheroma 1, burns and scalds 1, casualties 12, congestion of lungs 2, cirrhosis of the liver 2, diarrhea 1, drowned 1, dropsy 3, dysentery 1, eczema 1, epilepsy 1, erysipelas 3, hemorrhage from uterus 1, hernia 3, jaundice 1, obstruction of the bowels 2, edema of lungs 3, poisoning 2, pyemia 1, rheumatism 1, sclerosis arterial 1, septicaemia 5, smallpox 1, sarcoma, neck 2, stricture of esophagus 1, suffocation 4, suicide 5, syphilis 2, teething 1, tumor 1, unknown coroner cases 2, whooping cough 6 ..	43

Legislators at the Jefferson Hospital.—The members of the Legislative Committee on Appropriations were the guests of the Trustees of the Jefferson Medical College on Saturday, and were taken through the various departments of the institution with the view of demonstrating the need of an additional appropriation of about \$300,000 from the State, in order to make many necessary enlargements and improvements.

The demands upon the hospital and the inadequate facilities now predominating were shown, and the architect's plans for a new fireproof hospital exhibited to the visitors. The Trustees have acquired by purchase all the properties between the present hospital and the old college, and have arranged for the construction of a new building, with an isolated Maternity Department, of the most modern type of fireproof construction on the plot bounded by Tenth, Sansom, Clifton and Moravian streets.

The Founder of the U. S. Life Saving Service.—Dr. William A. Newell, aged 83 years, is still a practicing physician in Allentown, N. J. In 1839 Dr. Newell witnessed the wreck of the Austrian brig "Count Perasto," on Long Beach, Ocean County, south of Barnegat Inlet, on the New Jersey coast. Thirteen men of the crew were drowned and their bodies were washed up on the sands the following day. The force of the gale was so great that the vessel was driven far up on the beach, and yet for want of a rope to the shore the unfortunate men were unable to swim through the surf to safety, although the distance was but short. The incident suggested to Dr. Newell the idea that if some means were devised for throwing a line from shore across a wrecked vessel, many lives might be saved. He experimented with various kinds

of projectiles, and later, when serving in Congress from New Jersey, he secured legislation for establishing the Life Saving Service. Dr. Newell was afterwards (in 1857-59) Governor of New Jersey, and in 1861 was appointed by President Lincoln to be Superintendent of the New Jersey coast Life-Saving Service. From a small beginning this life-saving service has grown to be a great thing and now extends all along our coasts. To-day the Government appropriates more than \$1,500,000 annually for its support, and it is estimated that 250,000 lives have been saved by the methods which Dr. Newell originated, and in great part perfected, half a century ago.

The Kensington Hospital for Women.—During the month of March thirty-three patients were under treatment. There were thirty-two patients in the Hospital March 1st, and thirty-five are under treatment at the present time. There have been twenty-four abdominal sections and forty-one plastic and other operations during the month. In the Dispensary there have been fifty-three new patients, who have paid one hundred and ninety-four visits.

Fangothorapy.—Dr. W. C. Hollopeter, Professor of Pediatrics at the Medico-Chirurgical College, presented a paper on the above subject to a recent meeting of the Philadelphia County Medical Society. Fango is a grayish-brown slime or mud obtained from certain Italian lakes. It contains iron, sulphur, magnesium, lime, etc., and its properties are not lost by transportation. Its use is indicated in diseases of the muscles, rheumatism, gout, neuralgias, paralysis, etc. Local application to the part affected is made, a layer 3 cm. thick, at a temperature of 98 degrees to 120 degrees being used, the patient being placed between blankets to maintain the heat. After one-half to one hour the fango is easily removed by a tepid bath. Several cases in which this treatment gave good results were reported. Among them were cases of rheumatism, synovial swelling of the knee, gastric disturbances, etc. Dr. C. W. Burr said that the indications for the employment of this material were the same as those for a hot poultice. He considers it of no value in diphtheritic or spinal-cord palsies. The chemical composition of the mud probably plays but little part in the effect produced.

The Philadelphia Polyclinic and College for Graduates in Medicine.—Special Week in Ophthalmology, May 20th, 1901. During this week, in addition to the regular work on the eye and its diseases, given in the Clinics, there will be a number of extra hours of demonstration, clinical conferences, and lectures devoted to the subject of ophthalmology.

College of Physicians.—Section on Medicine.—The first case exhibited at the regular meeting of April 8 was one of **sacculated aneurism of the carotid artery of the right side.** The patient was an old colored man who has had the aneurism only a few years.

Dr. J. A. Scott exhibited a case of **endocarditis from typhoid fever.** The condition developed during a mild attack of typhoid fever in which the temperature became normal on the 28th day. The heart became irritable and nose-bleed occurred once. The diagnosis was based on the occurrence of cardiac symptoms, a systolic murmur which appeared during the third week of the disease and which still persists and is increasing, and on the leukocytosis which was as high as 15,000. Drs. Hare and Tyson considered the case to be rather one of relative insufficiency. Dr. Packard believed it to be one of endocarditis. Dr. Eshner saw no reason why endocarditis, as well as phlebitis and arteritis might not occur in typhoid fever. Dr. A. O. J. Kelly reported a case of **enlargement of the spleen and liver which has no other symptoms.** There are some points which resemble the cases of splenomegaly reported by Brill. Dr. S. M. Hamill exhibited photographs of a woman who had a **thoracic aneurism** since 1898. Recently a large multilocular intracavitary cyst was removed. No untoward result from the anesthetic occurred. Dr. J. M. Sailer reported a case of **aortic regurgitation** having a **flint murmur.** The theories regarding the cause of this murmur were reviewed. It was suggested that the condition was one of relative stenosis caused by the dilated condition of the ventricle. Dr. D. J. Milton Miller ex-

hibited specimens showing a **multiple thrombosis from a case of aortic and mitral disease.** The thrombus involved the innominate, external and internal jugular, and axillary veins as well as some smaller ones.

Lying-in-Charity Hospital.—The Lying-in-Charity Hospital of Philadelphia has been fitted out with a Pathological Laboratory. This laboratory has been provided with all the appliances necessary for the examination and preparation of tissues. The laboratory is under the direction of the pathologist of the Hospital, Dr. Fred. J. Kaltefleiter.

Philadelphia Hospital.—The Bureau of Charities has elected a dental staff constituted as follows: Dr. R. H. Nones, Dr. M. H. Cryer, Dr. J. Norman Brownell, and Dr. Thomas C. Steinwagen, Jr.

Dr. J. H. Grove.—Dr. John H. Grove, a well-known physician, died after a brief illness, aged 76 years. Dr. Grove was born in Maytown, Lancaster county, January 13th, 1825. His father was Christian Grove and his mother Elizabeth Heistand Grove. His ancestors were natives of Geneva, Switzerland, from which place they removed to The Hague, where they resided for a short time, after which they emigrated to America in 1865, locating in Pennsylvania.

After receiving his preliminary education in the public schools of his native county, Dr. Grove took a course at the Barnet Academy, in Marietta. He then entered the Medical Department of the University of Pennsylvania, graduating in 1849. He received the degree of A. M. from La Salle College, this city, and of LL. D. from Manhattan College, New York.

Soon after graduating he commenced the practice of his profession in Marietta, where he continued until the outbreak of the Civil War. In 1861 he received the appointment of Brigade Surgeon in the United States Volunteers, with the rank of Major. He was later breveted a Lieutenant Colonel and served until 1865.

In 1867 Dr. Grove commenced the practice of his profession in this city. During his long residence here he often contributed articles to medical journals. Immediately after the building of St. Agnes's Hospital he was chosen Medical Director, at the same time holding a similar position at St. Mary's Hospital, which positions he held for several years.

In 1899 Dr. Grove presented a handsome memorial chapel to the Presbyterian Church at Marietta, Pa., where he will be buried on Wednesday.

He was a fellow of the College of Physicians, also a member of the Association of Military Surgeons of the United States, the Legion of Honor, Union League, American Medical Association, Pennsylvania Medical Society, Philadelphia County Medical Society, the Pathological Society of Philadelphia, the General Alumni Society of the Medical Department of the University of Pennsylvania, the Alumni Society of Manhattan College, the Medical Club of Philadelphia, Loyal Legion and Meade Post, G. A. R.

NEW YORK.

New York Neurological Society.—Stated Meeting March 5, 1901, Joseph Collins, M. D., President. Dr. Joseph Collins presented for diagnosis and discussion a boy of ten years who presented a complex of symptoms which could not easily be placed under any one designation. He was one of twelve children, seven of whom had had in infancy marasmus or gastro-intestinal disorders. The present ailment had begun about nine months ago, at which time the boy had commenced to "hop." He complained of pain in the great toe of the left side, and also of pain in the precordial region. He had been taken to the Mt. Sinai Hospital and while there it had been noted that there was some stiffness or weakness in the lower limbs on walking. This impairment of motion had steadily increased, so that at the present time he was practically unable to walk more than a few steps. According to the history, there had been early in the disease great difficulty in commencing the act of micturition. At present there were no symptoms referable to the bowel or bladder. He has a peculiar waddling gait, and when standing, there is a typical flat foot. There is a peculiar knocking together of the thighs. The spasticity of the gait had been found, on closer examination, to be more apparent than real. There is a marked ankle clonus. There are no sensory

disturbances. He gets up from the lying position as children do in the early stages of progressive muscular dystrophy. These symptoms, the speaker said, seemed to point distinctly to a lesion in the spinal cord in the crossed pyramidal tracts.

Dr. B. Sachs said that he had been much interested in this boy at the time he had been in the hospital. The combination of the waddling gait, so characteristic of the dystrophy, with an increase in the reflexes, seemed to be especially unusual. When the boy was stripped, it seemed to him very evident that he had progressive muscular atrophy of the Landouzi type. In addition to this he thought there was a subacute myelitis, possibly of traumatic origin. There could be no question that the calves are hypertrophied. This diagnosis had been arrived at only after careful observation for a period of several weeks. The frequent falls which such children have would easily explain the occurrence of a subacute myelitis. The spasticity had been more marked nine weeks ago.

Progressive Muscular Dystrophies with a Report of a Post-Mortem Examination.—Drs. B. Sachs and Harlow Brooks presented this paper. The authors stated that it could not be denied that there was any sufficient distinction between the amyotrophies and the dystrophies. In former years much stress had been laid on the muscular structure. Hypertrophied fibres were found in abundance in dystrophies, whereas in the amyotrophies these fibres were not found. But later it had been shown that the hypertrophied fibres were found in other diseases than dystrophies. It was also a question whether the gray matter of the cord was affected in the primary dystrophies. The case to be reported was one of progressive muscular dystrophy of fifteen years' duration, yet the structural changes, as demonstrated by the latest methods of staining, were very slight. The patient had been admitted to the Montefiore Home eleven years ago at the age of twelve years. Early in life the parents had noticed peculiar movements of the head and eyes. He had been in good health up to about the age of ten years, when he had fallen and broken his leg. At the age of twelve years, after an attack of typhoid fever, it had been noted that the calves were decidedly hypertrophied. The head was enlarged and exhibited certain movements. There was a marked atrophy of all the muscles of the shoulder girdle, arm and forearm. The deep spinal muscles were intensely atrophied. The thigh muscles were atrophied. The case became an extreme illustration of a progressive muscular disease of the pseudohypertrophic type. The lad's intelligence was fair. Dr. Brooks said that at the autopsy the organs were normal with the exception of an acute pneumonia and a slight myocarditis. There were no gross lesions of the brain or spinal cord. No lesion of the smooth voluntary muscular tissue could be found anywhere in the body. The psoas muscle showed extensive fibrosis. The muscles of the back all showed extensive fibroid replacement, and in places, there was a replacement by yellow fat. The trapezii were very extensively invaded. The most extreme changes were in the muscles of the calves, where normal muscular tissue was lost. The autopsy had been done twenty-four hours after death, and at that time there had been no evidence of post-mortem decomposition. On microscopical examination, the muscles showed extensive replacement with areolar tissue of the adult type. In the calf, occasional remnants of voluntary muscle were found. Most of the fibres of the psoas muscles were either larger or smaller than normal. The coarse striae could usually be made out. The changes in the other voluntary muscles were of the same character, though varying in extent. In the occipital muscles the amount of connective tissue hyperplasia was less, but nuclear proliferation was prominent. Examination of various portions of the smooth muscles failed to show degeneration or hyperplasia of the connective tissue forming its framework. The heart muscle showed much less connective tissue increase than had been expected from the gross examination. The cardiac muscle was in a very natural condition, there being no atrophy, no abnormal pigmentation or abnormal nuclear activity. The blood vessels in the various tissues showed uniformly an increase in the connective tissue. No evidences of new vessel formation were found. Numerous peripheral nerves were examined,

but no appreciable degeneration of fibres was discovered. Only a few of the spinal ganglia had been properly prepared for examination, but these few showed a shrinkage of the ganglion cells similar to that produced by fixing agents. The irregular perilymphatic spaces were, however, found filled in with proliferating capsular cells, apparently that this was not an artefact, but a distinct process. Apparently the connective tissue of the ganglia had been increased. The connective tissue throughout the entire cord was found to be increased. The blood vessels of the cord were universally congested, but this was apparently of a hypostatic nature, due to the position of the patient before death. Nothing in the nature of a systemic degeneration of the fibres was found at any level. In the cervical region of the ganglion cells in the anterior horn showed a slight nuclear eccentricity. The dendrites universally retained their power to respond to the stain. Occasionally the achromatic elements stained to a slight degree. Eccentricity of the nucleus was found more commonly in the dorsal cord than elsewhere. Lesions in the cells of the posterior horns were more infrequent than in the anterior horns. The most common lesion was a finely granular subdivision of the plaques, usually not involving the entire cytoplasm. A few of the lumbar cells showed an unusual amount of brown pigment collected about the nucleus. The chief lesions were (1) Extensive atrophy, which affected apparently all of the voluntary skeletal muscles and was confined to these muscles; (2) the production of areolar connective tissue and adipose; (3) slight general perivascular hyperplasia; (4) moderate interstitial myocarditis; (5) extensive degenerative changes in a few of the posterior root ganglia, and (6) rare changes in the cytoplasm of the ganglion cells of the spinal cord. The complete absence of the changes in the smooth muscles showed that the disease process was strictly localized in the voluntary muscular system. The authors did not look upon the connective tissue increase as an essential feature of the pathological process, but as an example of a universal function of this tissue to take the place of any tissue which had been removed. The perivascular connective tissue hyperplasia was very slight, and could not be considered as typical of the disease or as produced by it. Possibly the moderate myocarditis was associated with the connective tissue hyperplasia of the blood vessels. It did not seem to be in any way connected with the factors producing atrophy of the voluntary muscles. The changes in the posterior root ganglia seemed to be of great significance, though it was not clear that they bore any direct relation to the changes in the voluntary muscles. These degenerations seemed to be secondary in their nature, and dependant upon death or disease of certain portions of the neuron. A process similar to this occurred after amputation. There were, therefore, no evidences of tract disease. The cytoplasmic degeneration of the ganglion cells in the cord were rare, and might represent the early stage of post-mortem change. Dr. Sachs said that these findings did not indicate that the cause was to be found in the gray matter of the cord. The disease represents a primary affection of the muscular fibre. The occurrence of stigmata of degeneration in so many cases of this dystrophy would lead one to think that these should be broadly classified under family affections. The question arose as to whether these muscular dystrophies were essentially progressive, and the statement was made that in every case the possibility of great improvement by systematic exercise should always be kept in mind in the early stage. Two illustrative cases were briefly reported which had been followed for many years.

Dr. C. L. Dana said that so far as the dystrophies were concerned, which were not strictly of the so-called pseudohypertrophic type but rather of the leg type, it seemed to be a well known fact that many of them cease to progress and live for many years in comparative comfort. He had personal knowledge of two families in which there were six or seven persons, going through three generations, who were afflicted with the leg or arm type of dystrophy. Some had lived to old age with only an inability to use the upper arm or perhaps the thigh muscles. One of these cases had been seen at many clinics in this city when thirty-nine years of age. The atrophies had begun at the age of nineteen, and had reached their height at about the age of twenty-

nine. His weight had been reduced to eighty-eight pounds. A fairly hopeful prognosis could be given in this class of cases especially when the atrophies do not begin very early in life. In his experience with pseudomuscular hypertrophy there had been only one case in which the disease had been really checked. This person was a lady of twenty-three in whom the trouble had begun at the age of eighteen. She had presented all of the typical symptoms of pseudohypertrophy of late development. He had put her upon systematic exercises, and as a result the disease had not only ceased to progress, but she had absolutely improved. In another case which had been faithfully treated by exercise and massage for four years, there had been continued progress. Dr. Dana said he would like to have Dr. Brooks explain why there should be so much fibrosis in these cases. It might be that in the death of the muscle fibre an irritant poison is formed, and that this gives rise to the increased proliferation. There was a striking difference clinically between a typical spinal atrophy and an ordinary dystrophy, and he believed these diseases were very different in their origin also. The hereditary cases were of a type which is quite distinct from that of the acquired forms.

Anti-Spitting Crusade.—The medical profession is indebted to Magistrate Mott, of New York City, for enforcing the ordinance against expectorating in public vehicles. Some communities have adopted the plan of having the conductor present to everyone violating the ordinances a small card on which is printed the legislative restrictions against promiscuous "spitting."

First Aid to the Injured.—The annual meeting of the Society for Instruction in First Aid to the Injured was held recently in New York city. The annual report, which was read by President Charles H. Marshall, shows that over 13,000 persons had been instructed by the society since its beginning. President William H. Baldwin, Jr., of the Long Island Railroad, stated that the instruction given to the employees of the road last year was very beneficial.

The New York School of Clinical Medicine.—Special lectures at the school will be held as follows: April 5th, Examination of the Male Urethra by the General Practitioner—Clinical Demonstrations, by Ferd. C. Valentine, M. D.; April 12th, Medical Questions of the Responsibility of Alcoholics, Opium and Other Drug Takers, by Thomas D. Crothers, M. D.; April 18th, Complicated Fractures: Diagnosis and Modern Treatment, by Thomas H. Manley, M. D.; April 26th, Diagnosis and Surgical Treatment of Prolapsed Kidney: With Clinical Demonstrations, by Augustin H. Goelet, M. D.; May 3rd, Treatment of Strangulated Hernia, by Carl E. Pfister, M. D.; May 10th, Pelvic Trillogy in the Diagnosis of Diseases of Women, by A. Ernest Gallant, M. D.; May 17th, The Technics of Major and Minor Amputations, by Robert H. Cowan, M. D.; May 24th, Treatment of Obesity, by Heinrich Stern, Ph. D., M. D.; May 31st, Diseases of the Stomach—Practical Examinations and Treatment—Demonstrations on Patients, by Freeman F. Ward, M. D.; June 7th, Psoriasis and Acne—Effective and Practical Methods of Treatment—Clinical Demonstrations, by W. R. Inge Dalton, M. D.

Manhattan Dermatological Society.—A regular meeting was held on Friday evening, April 5th at the residence of the Chairman, Dr. Wm. S. Gottheil. Dr. Sobel presented two cases of *pityriasis maculata et circinata* or *pityriasis rosea*, the first in a girl of twelve, the second in a boy of eight. Both showed typical patches on the face. The first was a classical one, the second presented in parts a close resemblance to seborrheal eczema. The condition was very itchy. He has frequently seen the disease confounded with syphilis. Recently he had observed a number of these cases in children under ten years of age. Dr. Weiss remarked that if one scratch an erythematous patch with the finger nail it becomes scaly. This test he considers almost pathognomonic. Dr. Gottheil said that the name *rosea* carried little meaning with it. Dr. Gottheil demonstrated an elaborate apparatus for the phototherapeutic treatment of dermatological lesions.

Dr. Geyser presented a case of extensive *lupus vulgaris* of the face successfully treated with the X ray. The right side of the face now showed a smooth, soft shining cicatrix. The left side was in the process of repair. On this side

a mild degree of alopecia had resulted. Each seance lasts 7-10 minutes and is followed by the static spray. This is the fourteenth case so treated and all have been successful. Dr. Weiss showed a case of *mollusca fibrosa*, showing the development of the lesions; some of these were more apparent to the touch than to the sight, some were sessile, some pedunculated, others again were soft. Dr. Ochs remarked that such cases often do well with asiatic pill. Dr. Gottheil presented a case for diagnosis. A young boy showed under the right arm pit a large growth consisting of tuberculous excrescences, very dark in color and for the most part dry. There were a few isolated patches to the outer side and on the inner side of the forearm a row of similar lesions. No secondary disturbances were noted. Dr. Weiss said that this was a rare and interesting condition, *acanthosis nigricans*. The region of the axilla is characteristic. Dr. Sobel said that while various conditions could be thought of the linear condition or the forearm led him to diagnose nervous linearis verrucosus. Dr. Gottheil stated that the growth did not correspond to *acanthosis nigricans* and is inclined to call the condition, *naevus unis lateris* or *naevus papillomatosus*.

Dr. Sobel presented a patient with diffuse dermatitis and pigmentation following the use of a two per cent. chrysarobin ointment for psoriasis. He prefers to use collo-dium or traumaticin.

Dr. Gottheil showed a gummatous deposit in the sternocleidomastoid muscle and in the clavicle. Also a case of undoubted disseminated cutaneous sacromata, corroborated by microscopic examination and a second one in which the diagnosis rested between syphilis and a beginning sarcoma cutis.

DELAWARE.

Small-Pox in Delaware.—The epidemic of small pox in the State is on the decline. Although about one hundred cases were reported. Of these 53 occurred in Seaford, 3 in New Castle, 15 in Concord, 3 in Bethel, and 7 are at the pest-house at Farnhurst. The others are scattered throughout the lower part of the State. Most cases are varioloid but there are a number of typical ones, and several terminated fatally. The State Board of Health has been very active and efficient in suppressing the epidemic. Dr. Lowber, the secretary of the board visited all the infected places, instituting quarantine whenever necessary and looking after proper disinfection. It is noteworthy that the town most affected is Seaford, which is blessed with an unusual number of antivaccinationists. Forty families are quarantined and supported by the town, Dr. Dawson having been placed in charge of the district.

The State Board of Health.—The three vacancies which occurred in the board were not filled by the governor, owing no doubt to the fact that physicians are not very anxious to serve now when they would have to expose themselves to small-pox. Dr. E. W. Cooper, of Camden, one of the most active members and the president of the board was reappointed. Although of different faith, the governor was forced to feel that the doctor could not be dispensed with. He has been serving on the board for the last ten years, and always proved equal to his tasks no matter how hard they were. Dr. Ellegood, of Concord, will probably also be reappointed. There is a feeling among prominent men that the members of the board that proved efficient in time of need are the ones whose services should be requested regardless of party.

NEW ENGLAND.

New Hospital for Insane.—On account of overcrowding the State Hospital for the Insane at Augusta, Me., the erection of a new hospital has begun six years ago at Bangor. Thus far \$440,000 has been expended, of which \$35,000 has been advanced by the Governor from his private means, and the new hospital is still incomplete. The Legislature is to be asked for an appropriation of \$200,000.

American Neurological Society.—The twenty-seventh annual meeting of the American Neurological Association, will be held at the Boston Medical Library.

CHICAGO AND WESTERN STATES.

American Academy of Medicine.—The twenty-sixth annual meeting of this society will be held at the Hotel Aberdeen, St. Paul, Minn., on Saturday, June 1, 1901, at 11

A. M. (Executive session); the open session beginning at 12 M. and continuing through Monday, June 3d. The principal features of the meeting will be a symposium on "Institutionalism;" and another on "Reciprocity in Medical Licensure." Series of valuable papers on both topics have been promised, as well as interesting papers on some other subjects. The President's address (Dr. S. D. Risley, of Philadelphia) will be delivered on Saturday evening, June 1st, and the Annual Social Session held on Monday evening, June 3d.

The St. Paul "Special."—Arrangements are being made for a special train from New York to the St. Paul Meeting, to leave New York city, Saturday, June 1st. Parties who wish to use this train in making the journey will communicate with Dr. F. H. Wiggin, 55 W. Thirty-ninth street, New York city, for further information.

Preparations for the St. Paul Meeting.—The *Journal of the American Medical Association* states that those who desire to attend the meeting in St. Paul, need have no fear that the city will be overcrowded, or that there will not be sufficient good accommodations for all. The people of St. Paul are making extensive preparations to take care of the visitors, all will be provided for. A program of entertainment for the ladies is being arranged. St. Paul has quite a reputation as a convention city, and there is yet to be heard complaint of the management or lack of accommodation. St. Paul has a number of first-class hotels, several of which are situated in the business district, while others are on the hill in the residence portion of the city, and many of the citizens will be glad to open their houses to the city's guests. The women of St. Paul have already formed committees, made preliminary arrangements, and are preparing to help make this year's meeting of the American Medical Association a memorable one.

Helped to Populate Two States.—It is said that a passenger on a train between Portland, Ore., and Spokane, Wash., went into labor and was delivered of twins. The elder, a boy, was born in Oregon; the younger, a daughter, arrived an hour later, and is a native of Washington.

Restrictions in Indiana.—In Indiana a regular licensed physician, who removes his residence to another county, must obtain a license from the clerk of that county, or he can not recover payment for his professional services.

Small Pox Epidemic Caused by a Letter.—According to the officials in charge of the quarantine squad at Saginaw, Mich., an epidemic of small pox affecting in all 34 people, has been traced to a letter received by a young lady from a soldier of the United States Army, stationed in Alaska.

SOUTHERN STATES.

Farm for Tuberculous Convicts.—It is not generally known that the State of Texas has isolated her consumptive convicts, thus showing a proper appreciation of the modern idea regarding this most destructive of human maladies. The Wynne farm, on which the diseased prisoners are located, is a large plantation situated about two miles beyond Huntsville and is the property of the State. For several years it has been cultivated by convicts, but not until December, 1899, was it set aside for the exclusive occupancy of consumptives. On October 31, 1900, there were confined in the Texas Penitentiary, 4,109 convicts. Of this number there were: Whites, 1421; negroes, 2,226; Mexicans, 460; Indians, 2. Many of the whites came from the tramp contingent of the population, and are the class of beings who indulge in the common vices of the age, thus weakening the power of the system to throw off disease. Added to this, many of them lie in crowded and unsanitary jails for months, and even years, before commitment. As to the negro element it is well known that a large proportion of the race is particularly susceptible to tuberculosis. For the most part the Mexicans are from the salubrious prairies of the West. Consequently, when they are housed in the buildings of the prison the change of life seems to point them out as an easy prey to consumption. To the above evils may be added as of prime importance the fact that a great many consumptives are sent to

prison—some arriving in the last stage of the disease. The Wynne Farm is an ideal "consumptive camp." The buildings are admirably located and constructed, and everything about the place is kept scrupulously clean. The water is pure, and every convenience for bathing is provided. The food furnished is of the most suitable character, such as vegetables, fresh meats, poultry, cereals, milk, butter, etc. The men live and sleep in a capacious pavilion or stockade, where each enjoys as much breathing space as he would in a forest camp. The Wynn Farm convicts are required to keep clean—person, clothing and bedding. The buildings are frequently whitewashed and constantly fumigated. Doctor Fowler says the principal medicines used are cod liver oil, creosote, the hypophosphites and whiskey. On this farm no one is required to work beyond his strength. But all are required to go into the open air and sunshine when their strength admits of leaving the bed. Thus far results have been most gratifying. Many men who went to farm apparently in the last stages of consumption, and who were scarcely able to feed themselves, are now hearty and stout. A remarkable feature of the arrangement is that it is self-supporting. The farm is credited with garden, orchard and other products furnished the prison proper, and for the overplus sold in the markets. At present there are fifty-nine men at the camp, and in general appearance seem to be the healthiest men among the convicts. The crop now being worked by this force consists of 250 acres of oats, 250 acres of corn, thirty acres of tomatoes, eighteen acres of onions, besides seven modation. St. Paul has a number of first-class hotels, several acres of melons and cantaloupes and other feed and vegetable crops.

Rappahannock Valley Medical Association.—At a meeting of the Rappahannock Valley Medical Association held here Dr. S. W. Carmichael was elected president for the ensuing year and Dr. J. N. Barney secretary and treasurer. A paper on "Epidemic Influenza or Grip" was read by Dr. Carmichael and discussed by many of the members present.

Kentucky State Medical Society.—The forty-sixth annual session of the Kentucky State Medical Society will be held in Louisville, May 22, 23, 24, 1901.

Louisville.—The sum of \$5,000 has been appropriated by the Aldermen for three public baths.

Alabama Medical Association.—The Alabama Medical Association will meet at Selma, Ala., April 16th to 19th.

New Orleans Polyclinic.—On account of various requests the Sessions of the Polyclinic will be continued to May 31st, instead of May 11th, as announced in catalogue.

Richmond, Va.—The section of Halifax Co., Va. known as "South of the Dan," is again visited by small-pox. Heretofore the disease was confined almost entirely to negroes, but now the whites have it also. There are 20 cases reported in this neighborhood and two deaths have occurred. The magistrates have ordered several localities quarantined.

Law Against Employment of Cream of Tartar.—A measure has been introduced in the Legislature of Arkansas prohibiting the sale of bitartrate of potash either alone or combination with bicarbonate of soda for the purpose of leavening or otherwise preparing food products, under a penalty of a fine of \$500 and six months' imprisonment.

Florida Medical Association.—The twenty-eighth annual meeting of this Association will be held in Jacksonville, April 10th, under the presidency of Dr. William L. Hughlett, of Cocoa. Dr. Jay H. Durkee, Jacksonville, is chairman of the Committee of Arrangements.

CANADA.

Toronto.—The contagious diseases report for March, for Toronto, is as follows: Diphtheria, 77 cases; scarlet fever, 97; typhoid fever, 6. The figures for February were: Diphtheria, 91; scarlet fever, 87; typhoid fever, 2.

MISCELLANY.

Drug Habits in the United States.—*The London Lancet* of March 2nd, 1901, contains the following notice: "The New York School of Clinical Medicine has established a special department of neurology, of which Dr. T. D. Crothers, of Hartford, Conn., has been elected professor—viz., the study of the neuroses and psychoses of alcoholism and of drug habits. Dr. Crothers is announced to deliver immediately a course of clinical lectures on inebriety from alcohol, opium, chloral, cocaine and other narcotics. These lectures appear to be timely, for the disease dependent upon or associated with the abuse of alcohol, opium, chloral, cocaine, and other narcotic drugs are steadily increasing in the United States of America, and the demand for special treatment in institutions and retreats is becoming more pressing every year.

Monstrosity.—M. Lannelongue presented at the meeting of the Académie de Médecine a Hindoo boy, aet. 8, well developed, but who had attached to the epigastric region a body without a head, constituted by a trunk and four limbs incompletely developed. The palpation of the parts revealed a certain number of vertebrae, the iliac bones, and a rudiment of a skeleton of the limbs. No trace of intestines could be found, but the sexual organs, which were that of the male, were somewhat developed, and both subjects urinated at the same time.—[Exchange].

Obituary.—Dr. Charles R. Stoddard, in California on March, 1901, aged 65 years.—Dr. George Hayward, at Boston, Mass., on March 30, aged 82 years.—Dr. George P. Jones, at East Newmarket, Dorchester county, Md., on April 2, aged 55 years.—Dr. Merritt H. Chandler, at Woodstock, Vt., on April 6, aged 57 years.

RUDOLPH VIRCHOW FUND.—On October 13th, 1901, Rudolf Virchow will be eighty years old. When he completed his seventieth year a fund was started in his honor to enable the great master to facilitate scientific research by establishing scholarships, and by encouraging special medical and biological studies. Contributions to that "Rudolph Virchow Fund" were furnished by those in all countries interested in progressive medicine, as a homage to the man whose name is always certain to arouse admiration and enthusiasm. In Berlin a large Committee containing among others the names of A. Bastian, v. Coler, A. Entenburt, B. Fraenkel, O. Israel, Fr. Koenig, C. Posner and W. Waldeyer has been formed to call for contributions which are to be added to the original "Rudolf Virchow Fund" so as to increase its efficiency. The Committee expresses the opinion that in no better way, and in none more agreeable to the great leader of modern medicine, can his eightieth birthday be celebrated, and ask for the sympathy and co-operation of all those engaged in the study and practice of scientific medicine all over the globe. The undersigned have formed a sub-committee for the purpose of making the American Profession acquainted with the intentions of the Berlin Committee, and urge their colleagues to participate in honoring the very man who has done more, these fifty years, than any other to make medicine a science and international. Subscriptions should be sent to their secretary, who will receipt therefor. Charles A. L. Reed, President of the American Medical Association; Henry P. Bowditch, President of the Congress of American Physicians and Surgeons; William K. Welch, John-Hopkins University; Robert F. Weir, President of the New York Academy of Medicine; A. Jacobi, 110 West 34th Street, Secretary.

Changes in the Medical Corps of the U. S. Army, for the week ending April 6, 1901:

THOMAS W. BATH, acting assistant surgeon, will proceed to his home, La Harpe, Ill., for annulment of contract. S. O. 63, March 19, D. Cal.

VERDO B. GREGORY, acting assistant surgeon, will proceed to his home, Dam, Wis., for annulment of contract. S. O. 63, March 19, D. Cal.

JAMES W. MADARA, acting assistant surgeon, will proceed to his home, Lexington, Ky., for annulment of contract. S. O. 64, March 20, D. Cal.

MAJOR HENRY D. THOMASON, surgeon, will proceed to Benicia Barracks, Cal., where he will report for temporary duty at that post during the absence of acting assistant surgeon Charles Y. Brownlee. S. O. 65, March 21, D. Cal.

porary duty at that post during the absence of acting assistant surgeon Charles Y. Brownlee. Upon the return of acting assistant surgeon Brownlee to Benicia Barracks, Major Thomason, surgeon, will stand relieved from temporary duty at that post and will proceed to San Francisco, Cal., for further orders. S. O. 65, March 21, D. Cal.

HENRY KIERSTED, acting assistant surgeon, is granted leave for one month. S. O. 65, March 21, D. Cal.

CAPT. FREDERICK W. COX, A. S., is relieved from temporary duty at the Army general hospital, Presidio, and will report to the commanding officer, squadron 6th cavalry, for duty with that command on the Army transport Hancock, to sail for the Philippine Islands. Upon arrival at Manila, Capt. Cox will report for assignment to duty. S. O. 66, March 22, D. Cal.

CAPT. FRANK P. KENYON, A. S., is relieved from temporary duty at the Army general hospital, Presidio, and will report to the commanding officer, battalion 7th infantry, for duty with that command on the Army transport Hancock, to sail for the Philippine Islands. S. O. 66, March 22, D. Cal.

CAPT. HENRY A. LITTLEFIELD, A. S., is assigned to temporary duty with troops on the Army transport Hancock, to sail March 25. Upon arrival at Manila, Capt. Littlefield will report for assignment to duty. S. O. 67, March 23, D. Cal.

FREDERICK C. JACKSON, acting assistant surgeon, is granted leave for one month, on surgeon's certificate with permission to apply for an extension of one month.

HOSP. STEWARD MILTON T. ESTERLY is relieved from further duty at the muster out camp on the military reservation of the Presidio, and will proceed to Fort Lisum, Alaska, for duty at that post. S. O. 67, March 23, D. Cal.

MAJ. WILLIAM BOWEN, surgeon, recently appointed, now in San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 29.

CAPT. EDWARD F. HERR, A. S., recently appointed, now on duty at Manzanillo, Cuba, will as soon as his services can be spared by the commanding general, department of Cuba, proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 29.

CAPT. W. HOEPFNER WINTERBERRY, A. S., recently appointed, will proceed from Fort Mason to San Francisco, and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 29.

CAPT. IRA A. ALLEN, A. S., recently appointed, is relieved from duty at the Army and Navy General Hospital, Hot Springs, Ark., to take effect upon the expiration of the leave granted him March 26, and will then proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 29.

CAPT. GEORGE W. DAYWALT, A. S., recently appointed, now in San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 29.

SURG. H. M. JAMES, acting assistant surgeon, granted leave March 1, is extended one month. H. Q. A., March 29.

CAPT. GUY G. BAILEY, A. S., recently appointed, now in San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 30.

MAJ. GEORGE W. MATHEWS, surgeon, is relieved from duty in the division of the Philippines, and will proceed to Fort Warren for duty, to relieve 1st Lieutenant Frederick M. Hartsock, A. S. Lieut. Hartsock will proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 30.

MAJ. HENRY C. FISHER, surgeon, is relieved from duty in the division of the Philippines, and will proceed to Jackson Barracks for duty, to relieve Maj. Aaron H. Appel, surgeon. Maj. Appel upon being thus relieved will proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., March 30.

FIRST LIEUT. HARRY L. GILCHRIST, A. S., is relieved from duty in the division of the Philippines, and will proceed to San Francisco, Cal., and report by telegram to the adjutant general of the Army for further orders. H. Q. A., March 30.

MAJ. JOHN M. BANISTER, surgeon, granted leave March 26, is extended ten days. H. Q. A., April 1.

CAPT. JUSTUS M. WHYATE, A. S., recently appointed, will upon the expiration of leave granted him March 12, proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment for duty. H. Q. A., April 1.

CAPT. FREDERICK C. JACKSON, A. S., recently appointed, now in San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., April 1.

CAPT. FREDERICK C. JACKSON, A. S., recently appointed, now in San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., April 1.

MAJ. EDWARD B. MOSELEY, surgeon: orders of February 14, which assign him to duty at Fort Sheridan are revoked. H. Q. A., April 2.

MAJ. EDWARD B. MOSELEY, surgeon, will upon the expiration of the sick leave granted him December 8, proceed to Denver, Col., and report to the commanding general, department of the Colorado, for duty as chief surgeon of that department, to relieve Lieut. Col. Henry Lippincott, D. S., G. Lieut. Col. Lippincott will proceed to Governors Island, and report to the commanding general, department of the East, for duty as chief surgeon of that department. H. Q. A., April 2.

MAJ. FRANCIS J. IVES, surgeon, is relieved from further duty with the United States forces in China and will proceed to Fort Sheridan for duty, to relieve Maj. George W. Adair, surgeon, who upon being thus relieved will comply with the requirements of previous orders. H. Q. A., April 2.

CAPT. FREDERICK A. W. CONN., A. S., recently appointed, will proceed from Philadelphia, Pa., to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., April 2.

THE following-named officers, recently appointed, now in San Francisco, Cal., will report for transportation to Manila, P. I., where they will report for assignment to duty: Maj. Frederick Hadra, surgeon; Capt. Francis J. Purcell, A. S.; Capt. Thomas W. Jackson, A. S. H. Q. A., April 2.

HOSP. STEWARD CLINTON F. HENDERSON, now at Fort Skaguay, Alaska, will be sent to San Francisco, Cal., for assignment to duty. H. Q. A., April 2.

ACT. ASST. SURG. JULIUS C. LEHARDY will proceed to Fort Wood and relieve Capt. Charles R. Gill, A. S., and Act. Asst. Surg. Adrian S. Williams. The latter will return at once to Fort Columbus for duty with the 1st battalion 11th infantry. S. O. 73. March 30, D. E.

COL. CHARLES C. BRYNE, A. S. G. H. A., April 3.

CAPT. EDWARD L. MUNSON, A. S., is relieved from further duty at Washington Barracks, and will proceed to Buffalo, N. Y., and assume charge of the exhibit of the medical department of the Army at the Pan-American Exposition to be held in the latter city. H. Q. A., April 3.

Changes in the U. S. Marine Hospital-Service, for the week ending April 6, 1901:

Official list of the changes of station and duties of commissioned and non-commissioned officers of the U. S. Marine Hospital Service for the 7 days ending April 4, 1901:

SURGEON D. A. CARMICHAEL, relieved from duty at Honolulu, H. I., and directed to proceed to San Francisco, Cal.—March 29.

SURGEON G. T. PECKHAM, granted 20 days' additional leave of absence on account of sickness—March 30.

ASSISTANT SURGEON HILL HASTINGS, to proceed to Bakersfield, Cal., for special duty—April 1.

ASSISTANT SURGEON C. H. LAVINDER, granted leave of absence for 10 days from March 26—March 27.

ASSISTANT SURGEON M. J. WHITE, to report to Surgeon J. H. White, for duty—March 29.

ASSISTANT SURGEON W. C. BILLINGS, to proceed to San Francisco, Cal., for special temporary duty—March 29.

ASSISTANT SURGEON D. H. CURRIE, to proceed to San Francisco, Cal., for special temporary duty—March 30.

ACTING ASSISTANT SURGEON R. S. PRIMROSE, granted leave of absence for 5 days from March 30—March 29.

Changes in the Medical Corps of the U. S. Navy, for the week ending April 6, 1901:

DR. A. E. PECK, appointed assistant surgeon from March 24, 1901.

MEDICAL DIRECTOR W. K. SCHOFIELD, placed on retired list, April 28, 1901.

SURGEON G. PICKRELL, granted sick leave for three months, from April 2.

ASST. SURGEON E. M. BLACKWELL, detached from Abarenda, upon reporting of relief, and home to wait orders.

ASST. SURGEON R. C. MARCOUR, detached from Havana Naval Station and ordered to Abarenda after temporary duty, on Philadelphia, May 4.

ASST. SURGEON E. DAVIS, granted sick leave for three months.

MEDICAL DIRECTOR G. F. WINSLOW, detached from Boston Navy Yard, April 18, and ordered home to wait orders.

MEDICAL DIRECTOR E. BOGERT, retired, ordered to the Boston Navy Yard, April 18th.

P. A. SURGEON E. R. STITT, commissioned surgeon from June 7, 1900.

PHARMACIST J. COWAN, detached from Glacier and ordered to the Manila and to additional duty at the Naval Hospital, Cavite.

SURGEON C. I. STOKES, detached from the New Orleans and ordered to the Solace upon her arrival on the Asiatic Station.

Official List of the Changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 days ended April 4, 1901.

D. A. CARMICHAEL, surgeon, relieved from duty at Honolulu, T. H., and directed to proceed to San Francisco, California, March 29, 1901.

C. T. PECKHAM, surgeon, granted 20 days additional leave of absence on account of sickness, March 30, 1901.

HILL HASTINGS, assistant surgeon, to proceed to Bakersfield, Cal., for special temporary duty, April 1, 1901.

M. J. WHITE, assistant surgeon, to report to Surgeon J. H. White for duty, March 29, 1901.

W. C. BILLINGS, assistant surgeon, to proceed to San Francisco, Cal., for special temporary duty, March 29, 1901.

D. H. CURRIE, assistant surgeon, to proceed to San Francisco, Cal., for special temporary duty, March 30, 1901.

R. S. PRIMROSE, acting assistant surgeon, granted leave of absence for 5 days from March 30, March 29, 1901.

The Treatment of Trachoma by Bichloride of Mercury in Glycerin.—U. Samtshuk (*Woennomeditsinsky Journal*, January, 1901), treated 186 cases of trachoma in soldiers. The majority of them were far advanced, the secretion in most being muco-purulent or purulent. Of 485 patients 266, or 54.7 per cent., recovered; the others were considerably improved. The solution employed was 0.12 gm of bichloride in 30 grms of glycerine. This was applied to the everted lids every second, third or fifth day, according to the severity or the progress of the case. The applications were made by means of a small cotton swab. The burning after each application lasted for a short time only, not more than half-hour. On the day following the addition of cocain, was used. If the conjunctiva was the addition of cocain, was used. In the conjunctiva was found much affected the author a 2-3 per cent. solution of nitrate of silver followed by irrigation with normal salt solution. The author believes that strong solutions of bichloride of mercury not only have an antiseptic but produce an irritation and consequent hyperemia of the conjunctiva, facilitating the disintegration and absorption of the granulations. [A. R.]

1.—Clubbe during the past 7 years has treated 49 cases of intussusception. Four of these cases were reduced successfully by injection and the remaining 45 were operated upon, 24 recovering. The average duration of time from the onset of the symptoms till the operation was performed in the successful cases was 24 hours, and in the fatal cases was 56 hours. These figures show the great importance of an early diagnosis and early treatment in these cases. Of the 49 cases 30 were ileo-colic, 3 colic, 1 enteric, and 6 double (ileum into ileum and both into cecum). In 4 cases, all fatal, resection of the bowel was necessary. In making a diagnosis the important symptoms are the sudden onset of pain with pallor, followed by vomiting. The pallor disappears and the pain returns at intervals. A normal bowel movement accompanies the attack, but is followed in a short time by a passage of blood, and it is this symptom which usually alarms the mother and causes her to seek medical advice. The general condition of the little patient is apt to be misleading. It may be listless or it may be playing about with its toys in the intervals between the pains, the temperature may be normal and the pulse but little accelerated. An examination of the abdomen will usually reveal the presence of a "sausage-shaped" tumor. The presence of this mass with the other symptoms will enable one to make an absolute diagnosis of intussusception. If because of the pain in the abdominal muscles are rigid and a satisfactory examination cannot be made, then the child should invariably be anesthetized. Examination per rectum is usually unsatisfactory. It, however, must be remembered that the colon may be invaginated into the rectum and presenting at the anus be mistaken for a prolapse of the rectum. Intussusception occurs not infrequently during attacks of diarrhea, and under such circumstances an improper diagnosis is frequently made. It is possible to have an intussusception with all the usual symptoms absent. If the intussusception is acute after 24 hours there will always be symptoms of intestinal obstruction.

Treatment. Clubbe finds injections very useful in cases of intussusception. In four out of his 49 cases reduction and recovery occurred from this means of treatment. In all cases diagnosed early this treatment should first be instituted, and although it may not result in a cure, it empties the lower bowel and enables the more perfect examination of the abdomen and a more successful operation, if this is found necessary. Before using the injection the child should be prepared for operation and an anesthetic

given. The tumor may reappear after apparently being relieved by the injection and then operation should be done. When the mass is small and confined to the right side of the abdomen, incision should be made to the right of the rectus muscle, but in other instances the incision should be median and extend both above and below the umbilicus. When the abdomen is opened the tumor should be delivered and reduction accomplished by squeezing the intussusciptions, traction of the intussusception being dangerous. Resection becomes necessary when reduction cannot be accomplished, or where the bowel has been so damaged as to render gangrene probable. Resection, however, should not be done unless absolutely necessary, as it greatly increases the danger. In making an anastomosis catgut is used in preference to silk, but bobbins or buttons are not to be commended. The after-treatment should be carefully looked into, and it must be remembered that children cannot bear post operative fasting as can adults, but must be fed within the first few hours after operation. Clubbe thinks it a mistake to keep the child too rigidly on the back. Very minute doses of morphia are usually required at varying intervals during the first 24 hours after operation. The abdomen is closed by silk worm gut sutures, which are not removed for 10 days. [J. H. G.]

2.—During the past few years Walsham has seen 7 cases of intestinal obstruction due to the reduction of a hernia en masse. He thinks the reduction en masse is much more apt to occur from the manipulation by the patient himself than by the attending physician. In each of the 7 cases reported the reduction was accomplished by the patient. Great stress is laid upon the necessity of making careful inquiry regarding the pre-existence of a hernia in all cases of intestinal obstruction, even where the abdominal rings show nothing on examination. In one of the cases reported the reduction en masse had been done 2 months before the development of symptoms of intestinal obstruction. In one case the patient had ruptured the bowel in reducing the hernia. [J. H. G.]

3.—Maunsell thinks that in cases of perforated gastric ulcer treated by operation the per cent. of recoveries in the hands of those accustomed to operate will be found to be between 45 and 50. The sooner the operation is done the better will be the chances of recovery. Of Mayo Robson's 6 cases 3 were operated upon within 24 hours and recovered, 3 after 24 hours and died. Of Ulster's list 8 cases were operated upon within 12 hours with 64 per cent. of recoveries, 6 after 12 hours with 33 per cent. of recoveries. The disease is more common in men than is generally supposed. Maunsell reports 4 cases of his own, 2 of which were operated upon within 13 hours and one recovering. The other 2 were operated upon respectively 19 and 31 hours after perforation and both died. In making a diagnosis the sudden onset of the symptoms upon some exertion is of great importance. Although the onset may be severe, not infrequently the patient is not incapacitated, one of the cases reported having walked to the hospital. The onset is frequently preceded, but not often followed by vomiting. The pain begins in the epigastrium and spreads, but does not shift its position. Thirst is not intense, and there is no restlessness, as is often present in severe hemorrhage. In muscular subjects distension is rare. The pulse does not aid one in making an early diagnosis. The "stomach note" does not exclude perforation as a perforation as perforated and a collapsed stomach are by no means synonymous terms. Liver dullness is diminished or absent in every case. Treatment. In every case in which a diagnosis of perforation is made should be operated upon, and in every case in which the condition is strongly suspected an exploratory incision should be made. The best time to operate is as soon after the diagnosis is made as suitable arrangements and surroundings can be had. It is never too late to operate unless the patient is moribund. In over 80 per cent. of cases the perforation will be in the greater peritoneal cavity. The stomach should be emptied by a catheter through the perforation. After closing the opening Maunsell places over it an omental graft. Where the soiling of the peritoneum is general he thinks that both douching and wiping with gauze are requisite in order to thoroughly cleanse the abdominal cavity. He does not think that douching alone will remove infection from the pelvis and from the upper surface of the liver. [J. H. G.]

4.—Child reports a case of hour-glass contraction of the stomach due to ulceration. All the symptoms which

this patient complained of pointed rather to a malignant disease of the stomach, and the operation was performed with the idea of doing a gastro-enterostomy. The anastomosis was done and the patient died on the fourth day after operation. The postmortem examination showed a stomach constricted in its centre, the opening between the two cavities admitting the little finger. The cardiac portion extended far up beneath the ribs and costal cartilages but at the time of operation because of its position, was not recognized. This case resembles closely one recently published by Dr. Martin and Mr. Pollard. The patient's ribs extended nearly to the iliac crest, and the interspace between the costal cartilages was very narrow, and Childe doubts whether it would have been possible to make an anastomosis between the cardiac portion of the stomach and the bowel. The anastomosis which he did make was between the pyloric portion and the small intestine.

[J. H. G.]

5.—Angus reports a case of ulcer of the stomach complicated by acute hematemesis. The patient was a 19-year-old girl who had suffered some epigastric pain after eating for 12 months. Occasionally vomiting had occurred, but she had never vomited any blood. The hematemesis occurred at 11 P. M., and the patient was immediately sent to the hospital and the abdomen was opened at 3.30 A. M. The greater peritoneal cavity was found in a normal condition. The lesser cavity was opened, and on the posterior wall of the stomach near the lesser curvature an indurated patch was found. The stomach was opened and the ulcer found opposite the patch mentioned. A purse-string catgut suture was passed around the ulcer, the bleeding being controlled in this way. The stomach wound was closed with three rows of catgut sutures; no drainage. Two weeks after the operation the patient developed a phlebitis of the left leg, and a week later the same condition occurred on the right side. The patient, however, made a good recovery. Angus does not think that the phlebitis was of a septic origin because the constitutional disturbance was slight, there was no pus formation, the condition disappeared and the vascular channels became reestablished. [J. H. G.]

6.—Althorp reports a case of gastric fistula in which he operated after the following method: The fistula was dilated to admit the finger, and through it was passed into the stomach several small sponges with silk ligatures attached. The fistulous tract was then sterilized with pure carbolic acid and an incision made two inches away from the opening into the peritoneal cavity. The adhesion to the abdominal wall was found to extend over an area of 3 by 1½ inches. The general cavity was protected by gauze pads, and the entire fistulous tract was excised. The opening into the stomach was closed and an omental graft placed over it. The patient died on the sixth day from pneumonia. The post-mortem showed no evidence of peritonitis and no escape of stomach contents. [J. H. G.]

7.—Horrocks reports a case of perforated ulcer of the stomach which was operated upon 8 hours after perforation, the patient making a good recovery. There was no indication of gastric ulcer before the perforation took place. The ulcer was near the cardiac end and close to the lesser curvature. There was no evidence of any exciting cause for the perforation. There was marked tension of the abdominal wall over the stomach, but no distension and the hepatic dullness was not diminished. [J. H. G.]

8.—Campbell and Wood report a case of subphrenic abscess which recovered after drainage through the abdominal wall. The case was complicated by an effusion of serum into the pleural cavity, which was removed by the aspirator on several occasions. [J. H. G.]

9.—Newbolt reports 4 cases in which he has used the Murphy Button with satisfaction. Two were cases of strangulated hernia requiring resection; one was a case of malignant disease of the pylorus in which he did a gastro-enterostomy; and the fourth case was one of intussusception. Recovery followed in all cases excepting the last. [J. H. G.]

10.—Savory and Nash report an interesting case of intestinal obstruction coming on after violent exertion, and in which subsequent abdominal section revealed the presence of a papillomatous ovarian cyst and a carcinoma of the small intestine. The cyst was removed at the first operation and resection of the small intestine done 12 days later. The patient made a good recovery. [J. H. G.]

11.—Groves reports the case of a girl aged 1 year and 8 months, who was suffering from distended abdomen and great emaciation. When the patient was about 1 year old she began to lose flesh and was constantly crying as if in pain. When first seen, she was extremely emaciated. There were no signs of rickets, tubercle, or syphilis, and the dental development was good. The abdomen was uniformly distended: was tympanitic to percussion; but there was no tenderness on palpation and no hard masses or tumor could be felt. Rectal examination showed nothing abnormal. The bowels were opened with great regularity two or three times a day; the stools were soft, but well formed and rather clay-colored. The temperature rose above 100 degrees F., and the patient refused her food. This continued for 6 days, when the child died. At the post-mortem examination the calibre of the ileum was suddenly reduced by a hard, unyielding stricture three-quarters of an inch long, which admitted a probe with difficulty. The other parts of the intestine were normal, but the mesenteric glands were slightly enlarged. The condition was most certainly congenital. [J. M. S.]

12.—Clarkson urges the consideration of Meckel's diverticulum as a cause of internal hernia, and suggests the importance of ascertaining whether or not the tube is a pervious one or only a simple fibrous band before resorting to its division. [J. H. G.]

13.—In the second Lettsomian lecture, Bruce continues his discussion of the diseases of the heart and the arteries in middle and advanced life. The uncomplicated effects of tobacco on young healthy hearts, as they present themselves clinically, are palpitation in every instance, a sense of irregular action, post-sternal oppression and pain in half the cases, and in 1 out of every 8 sufferers either angina or uncomfortable sensations in the left arm. Faintness or actual faints occurred in one-third, and giddiness and a feeling of impending death in a smaller proportion. Physical examination shows that the heart is of ordinary size in 50 per cent. of the patients; in a few it is very slightly enlarged; the precordial impulse is often very weak, but occasionally increased in force and frequency, and often irregular; the pulse tension, with insignificant exceptions is found low. Out of twenty such patients who complained of the heart, not one presented a cardiac murmur beyond a weak mitral systolic bruit, varying with posture or cubitus. As an exemplary case, a man of 40 will complain of his heart; he has smoked for years the strongest and blackest tobacco he could buy. His heart is not enlarged and the cardiac sounds may be described as ordinary were they not peculiarly irregular, the frequency changing every moment, and a falter occurring at short intervals. There is not a trace of murmur to be found in connection with the valves and orifices. At ages over 40, whilst palpitation is still the more common complaint, pain, including angina, is put forward more prominently, and so are faintness, actual faints, a feeling of impending death, and a sense of cardiac irregularity, each intermission being accompanied with a sudden stab through the precordia. In these subjects the heart is more frequently found to be large and feeble; the same weak systolic murmur is occasionally to be heard; the radial pulse is often irregular, and the vessel wall thick. Every cardio-vascular lesion that may happen to be found in tobacco smokers is not to be put to the credit of tobacco, nor should precordial pain, angina, faintness, and irregular pulse, in a man of 60 with a full-sized heart, be hastily regarded as evidences of grave disease without further inquiry as to the habits of the patient. The cardiac enlargement and large pulse may be nothing more than the result of a life of bodily and mental activity; the precordial distress may be the only result of tobacco. The alcoholic heart presents clinical characters as a whole very different from those of tobacco heart. The most striking and important of these are the evidences of actual pathological change in the size of the heart and the condition of the myocardium. Of 28 cases of alcoholic heart in only 2 were the hearts of ordinary size, and in both of these cases the patients were under 40 years of age. With hardly an exception the precordial impulse is weak, the sounds are small and feeble, and may be almost inaudible in 20 per cent. of cases a weak apex systolic murmur could be heard varying with posture and time of day, significant, no doubt, of leakage through a dilated mitral opening. The alcoholic heart is irregular and accelerated in about half the cases. The pulse tension is usually low; in one-third of the instances the radial artery

was sclerosed; in one-fifth of them there was slight albuminuria; the legs may be edematous. The complaints with which the patient comes to us are commonly palpitation of the heart, faintness or actual faints and precordial pain, but it is very interesting to observe that angina pectoris is rare in the alcoholic as compared with the tobacco heart in the ratio of 4 to 15 per cent. Instances of disorder and disease of the heart and arteries met in gouty subjects at or over 40 years of age. Out of 29 cases, 12 had suffered from ordinary articular gout, the other 17 had irregular gout. In no instance was there albumuria. In 23 of the 29 the heart proved to be enlarged either on one or on both sides. In less than half the number the cardiac action was feeble; in a small number the impulse was entirely imperceptible; the heart and pulse rate was ordinary; the rhythm was but seldom irregular. In 12 out of the 29 cases of gouty heart a systolic murmur was to be heard over the aortic area, the manubrium, and the right carotid, significant of disease either of the aortic arch or of the aortic valves. In 7 cases a more or less well developed systolic murmur was found in the mitral area, significant either of valvular atheroma and sclerosis or of leakage from valvular dilatation. When no murmur exists the cardiac sounds are commonly somewhat feeble and the second sound may be of ringing quality. The radial pulse is more often tense in the subjects of irregular than of regular gout, the great majority presented, distinct thickening of the arterial walls. Besides a distressing feeling of irregularity, fluttering or intermittency and dyspnea on exertion, men who are the subjects of gouty heart complain most frequently of precordial pain; women more often of palpitation and faintness or actual faints. In quite $\frac{1}{4}$ of all cases of gouty heart the pain is anginal, and such angina may be of the most pronounced type. Closely related to goutiness is a clinical type of disturbed metabolism characterized by corpulence and glycosuria. Of patients so affected who complained of cardiac symptoms, $\frac{3}{4}$ had a systolic aortic murmur, none of them a regurgitant aortic murmur, and nearly $\frac{1}{2}$ of them an ill developed mitral systolic murmur. In 11 cases of acute strain of the heart the heart in all but one was large, with feeble precordial impulse; the sounds were small and feeble, the aortic diastolic sound was often ringing; in but one case was there a murmur. With few exceptions the rhythm and the rate of the heart were ordinary. In half the cases the radial artery was sclerosed; in the majority the tension was not increased. Persons who strain their heart after middle life chiefly complain of precordial oppression, a sense of palpitation and irregular action of the heart, and pain, which may amount to angina. Of these 11 individuals, 7 were gouty. In the case of a person who has strained his heart in youth or early manhood and has never been quite well since, the heart is always found to be enlarged, in about $\frac{1}{2}$ of the cases it is irregular. It may be weak and beating at the ordinary rate, but in other instances it is increased both in force and frequency. In quite exceptional cases, endocardial murmurs are heard. High tension and sclerosis of the radial artery were respectively found in about $\frac{1}{2}$ of the cases. The patients complained most commonly of a distressing sense of irregular palpitation of the heart, and very commonly of precordial pain, but rarely of angina. Syphilis appears to account for a very considerable proportion of the more serious cases of heart disease that we meet with in older subjects, of course excluding chronic valvular disease originating remotely in endocarditis Syphilis as a cause of cardiovascular lesion is very often associated with other morbid influences, particularly strain and alcohol. In case of cardiovascular disorders and disease from nervous strain, the arterial tension is usually high; the radial artery is thick, sometimes markedly so; the heart enlarges; and in about $\frac{1}{2}$ of the cases a systolic murmur is to be heard either in the aortic or in the mitral area. [J. M. S.]

1.—In a brief summary of the housing question, Sykes states that in order to establish healthy housing for the people, our ideas must be cleared regarding two related but distinct factors. The first is a pressure of population in urban districts, whereby dwellings are compressed within the smallest limit. The remedy for this will be found by improving transportation between urban and suburban centers and by building additional houses in the suburbs. The second factor is the dilapidation of dwelling houses and the deterioration of the health of the inmates, whereby unsanitary areas are created. The remedy for this will be found in the reconstruction of the worst areas, the adaptation of the best streets and healthy flat-form of construction, and the institution of sanitary laws having the dwelling as the basic unit. [F. J. K.]

3.—Stevens discusses blackwater fever, emphasizing the methods of diagnosis and the causation of this disease. After examining the blood in a number of cases, he concludes that his own observations have shown him that malarial parasites are not necessarily found in the peripheral circulations in blackwater fever, but this does not prove that the case in question is not of malarial origin. The presence of pigmented large mononuclear leukocytes, are of importance from a diagnostic standpoint. The author believes that when the large mononuclear forms are above 20 degrees, there is abundant proof of malarial infection. The author therefore attaches great importance for diagnostic purpose, by the presence of pigmented leukocytes, and the leukocytic change. The following conclusions are drawn: That blackwater fever is essentially of malarial origin; the exacting factor, or the determining cause of this disease is quinine; blackwater fever may be prevented by protecting the individual from malaria; the important points in the prophylaxis are attention to clothing and the use of the mosquito net. [F. J. K.]

4.—Richardson reports three (3) cases of fulminating appendicitis, which he has operated upon with success. In each case there was a premonitory stage lasting for a few hours, during which the patient felt unwell and uneasy in the abdomen, followed by a sudden development of acute symptoms which somewhat subsided after several hours of severe pain. This subsidence was followed in 24 hours from the initial attack by violent and sudden increase of all symptoms, and a few hours later pus was found over the entire abdominal cavity with a perforated and non-adherent appendix. Robinson's rule in the first treatment is to apply hot fomentations to the abdomen, to administer morphia only in urgent cases and then to operate, unless there is an improvement in all the symptoms. He lays great stress on the fact that not only the pain should be less, but that the rigidity, anxious expression, etc., should also improve. He uses gauze as drainage, preferring it to a tube. The gauze is withdrawn on the fifth day, when it is accomplished with little pain. [J. H. G.]

5.—H. W. Dodd believes that in chronic glaucoma of central origin removal of the cervical ganglion apparently does not interrupt the connection of the eye. Either the connection is not established in this manner, or some other means of communication are established soon after the operation. The author's first case appeared in the *Lancet* of October 14, 1900, page 71. His second case, reported in the present paper, is that of an unmarried woman aged 44, who had chronic glaucoma in both eyes. Iridectomy had given no relief and the tension still remained plus 2 the visual field markedly and irregularly contracted, distinct signs of chronic glaucoma in the fundus and considerable pain and reduction of

vision. The ganglia were removed at different times. The operation performed was that described by Dr. Jonnesco as the "premastoid" one. The tension of the eye became immediately lower after the resection of the left ganglion and the pain relieved on that side. Similarly good results were obtained on the other side. Vision and visual fields improved. [M. R. D.]

6.—Dearden discusses the elimination of arsenic through the hair, and its relation to arsenical poisoning. The reason for the non-employment of this method for diagnosis is most likely explained on account of the difficulty of estimating the arsenic in the hair by the ordinary methods. The method employed by the author was Sanger's modification of the Marsh test: Samples of hair were taken from six males; two of these were from cases of arsenical poisoning; another was from a patient who had taken arsenic over an extended period (one-ninth of a grain daily), and three specimens were taken from healthy individuals. In one case of arsenical beer poisoning the arsenic was found in the hair to an extent of .3 in 10,000. In the individual who had been taking arsenic medicinally, the drug was found in the proportion of .3 in 10,000. Arsenic was detected in quantities too minute to be estimated in one gram (of hair substance) in the healthy individuals. From a medico-legal point of view the detection of arsenic in the hair may prove to be of immense value, for hair is one of the last parts of the body that undergoes decomposition. [F. J. K.]

7.—Maguire reports a case of measles complicated by laryngeal diphtheria which terminated fatally. The infant was 18 months of age and developed a typical exanthem, accompanied by characteristic symptoms of rubeola; a history of diphtheria infection could not be ascertained. As the disease progressed and it seemed to be pursuing an ordinary course, suddenly symptoms of dyspnea set in; the difficulty of breathing increased, the child was cyanosed and appeared to be in terrible distress. The possibility of membranous construction was considered, but after a most careful examination of the larynx, not a particle of membrane could be found. Tracheotomy was performed, giving the child some relief, but finally death occurred from collapse. The autopsy revealed a thick, tough membrane occurring the larynx and producing almost complete obstruction. It was proven by a bacteriologic examination that this infection was due to the diphtheria bacillus. [F. J. K.]

8.—Newman, in continuing the History of Renal Surgery, discusses nephrotomy and nephrectomy, giving the progress of each operation. [J. H. G.]

1.—Tyson gives the following conclusion regarding the use of chloralose: It is a prompt and safe hypnotic, its action being more prompt than any drug except morphine; it is more prompt and efficient in smaller doses than chloral. The author believes that further studies should be made upon this drug. Five grains is the maximum dose, which may be repeated in an hour; smaller doses should always be tried. [F. J. K.]

2.—Price considers the subject of the artificial menopause or post operative nervous phenomenon from the standpoint of the general practitioner. He remarks that unfortunately but a few of these patients are kept under treatment sufficiently long for permanent results after the operation. As a rule they are systematically treated only for a period of three or four weeks, and are then hurriedly returned home where everything is unfavorable for a favorable convalescence. The practice of early rising and early discharge after an operation favors post-operative sequelae and a tedious convalescence. The rest-cure would do very much for this class of patients. Under such a course of treatment the general improvement is marked; the patients eat and sleep well, are bright and cheerful, all their uncomfortable symptoms vanish, and they recover flesh and color rapidly. Systematic rubbing and massage should be added. [W. A. N. D.]

3.—Bulkley discusses the subject of syphilis as a non-venereal disease, and argues that so long as syphilis is regarded exclusively as a venereal disease it will be extremely difficult to control its spread. He urges that syphilis should be classified amongst the contagious diseases. He reviews the subject of the world wide distribution of this disease, and considers in detail the methods by which the disease is communicated to the innocent. Reference is made to three groups: (1) Marital syphilis; (2) Hereditary syphilis, and (3) Extragenital syphilis. He finally makes a plea for legal control of syphilis, stating that the most important point in the prevention of its spread will be found by considering it contagious and instituting measures to prevent dissemination similar to those used in checking other contagious diseases. [F. J. K.]

4.—Allen discusses the recent clinical observations on tinea versicolor. The author states that the disease, while rare in young individuals, has been observed below the age of ten by competent investigators. The writer cannot verify the statements of other observers, that tinea versicolor frequently occurs in individuals who suffer from phthisis or any other severe diseases. Patches of tinea versicolor, as he pointed out a year ago, frequently occur in the public region in both men and women; these patches may be regarded as a source of renewed infection in some instances. Recurrent infection in some instances may be ascribed to the fungus being present in the hair follicle. He believes the iodine test is valuable in distinguishing the pigmented areas of tinea versicolor from chloasmas, macular syphilides, exanthemata, erythemas, etc. However, the diagnosis is often difficult without the microscope. A report is given of a case of pityriasis nigra. In referring to the treatment of tinea versicolor, the author has found soap of itself capable of ridding the surface of fungus. He has used the following ointment with good results: 50 parts of an ointment made with calcium bisulphate in a saturated solution; 20 parts of lanolin and 30 parts of lard. [F. J. K.]

5.—Wende relates his experience with an epidemic of rabies, in Buffalo. The first case was observed in November, 1898, in the Kenmore section of the city; following this case, there were a number of isolated instances at varying intervals. From April 1st., 1899, until April 1st., 1900, there were 230 persons bitten by dogs; 37 persons were bitten by rabid animals, and 4 deaths occurred from hydrophobia. From the beginning of the epidemic until April, 1901, 4,429 dogs were disposed of. The most important and prominent clinical characteristics of the disease in the animals were the following: there was a changed behavior and an altered disposition of the animals;

they were irritable and restless; they showed a desire to swallow foreign bodies, such as stone, glass, wood etc. The animals showed a tendency to stray away from their homes. The most constant symptoms, especially from a diagnostic standpoint, was an alteration in the voice due to paralysis of the vocal cords. Another characteristic symptom was a tendency to snap and bite at imaginary objects, and there was also peculiar and furious aggression towards anything before them; the dogs did not shirk or retire from impending blows; they did not seem to show evidence of impending danger. The author states that a symptom heretofore undescribed was the appearance of the pouching out of the neck, due to spasm of the muscles of deglutition. The author makes a plea for municipal restriction of rabies. [F. J. K.]

6.—Mottet states that in order to solve the problem of legislation pertaining to pure food, a greater interest should be shown on the part of the medical profession. More careful researches and investigations should be made upon the physiology of digestion, absorption and assimilation; and that the profession should adopt certain definite and more reliable standards, which would embody fundamental principles. Finally in order to put into effect and carry out these principles, governmental legislation becomes necessary. [F. J. K.]

7.—Tracy recommends for transverse fracture of the tibia a splint of wood-plastic material molded to the leg after being moistened with water. This splint is applied next to the skin. Tracy holds that this method of treatment gives entire satisfaction, allowing of frequent inspection of the leg and of massage. [J. H. G.]

8.—Allports first calls attention to the anomalous positions of the abdominal viscera and to the changes brought about in the relations of the abdominal viscera by pathological conditions. Brief histories are recorded of 14 cases of Renoe Disease in which mistakes of diagnosis were made. Among these the kidney was taken for the spleen and the spleen for the kidney; the liver was found behind the colon in searching for a kidney, and the kidney lying against the anterior abdominal wall in front of the colon; the gall bladder was found in the loin and again in the iliac fossa and perinephritic abscess was mistaken for calculus and appendicitis, and finally an empyema was found to resemble renal cancer. Instances are recalled where renal calculus was treated for Bright's disease and other instances where the kidney was opened for stone and none found. After discussing these cases Allport makes the following deductions:

(1) The surgeon should not attach too great weight to the opinions and subjective symptoms of the patient unless these are borne out by the physical signs. (2) On the other hand, due consideration should be given to the statements of intelligent patients especially in cases where the objective symptoms are so abundant as to be confusing. Careless history taking is shown to be a source oftentimes of wrong diagnosis. In 2 cases of the 14 shown a history of traumatism was not elicited prior to operation and the neglect resulted in a diagnostic error. (3) In the presence of pathological conditions it is a mistake to place too great reliance on normal relations of the viscera. (4) It is an error to make a diagnosis on the presence of a condition which is recognized to be pathognomonic without carefully going into the history of the case and the other symptoms which it presents. Stress is here laid upon the great necessity of using every available source of information. Although a Skiagraph may fail to reveal a calculus under certain circumstances, it is a mistake to perform nephrotomy without making use of the X-Rays. The importance of a record of temperature and pulse is urged as a diagnostic means in all cases of suspected kidney disease. (5) Among the operative errors is mentioned the improper care of the ureter after nephrectomy. This organ should be ligated with catgut and brought separately into the wound after cauterization or, which is better, it may be inverted and stitched. Kidney stumps should not be

ligated with silk. Too deep incisions in the kidney substance are dangerous and jeopardize the subsequent integrity of the pelvis and ureter. Drainage should always be employed at least for a few days after nephrotomy. A kidney riddled with sinuses should always be removed.

These conclusions are well based on the illustrative cases submitted by the author. [J. H. G.]

9.—Wesener discusses the relation of indicanuria and oxaluria to gastro-intestinal fermentation. The author states that the main object of his article is to determine whether or not there is a relationship between excreted indican and oxalic acid, and what bearing these substances have upon gastro-intestinal fermentation. He reaches the following conclusions: (1) in normal urine traces of oxalates are present. (2) when oxalate crystals are found in the urine they usually suggest gastro-intestinal fermentation; however, it must be borne in mind that food which is rich in oxalates must be excluded. (3) When oxalate crystals are found in abundance they do not indicate a high acid percentage, for the reason that there may also be found oxalates of lime in solution. (4) Often indicanuria is associated with oxalate crystals, but this is not invariably the case. (5) Hyperacidity, whether due to hydrochloric acids or acids of fermentation, is an aid to putrefaction. (6) In certain gastro-intestinal derangements, whether due to excess of hydrochloric acids or fatty acids, indican and oxalic acid are increased. (7) The symptoms of oxalic acid diathesis are due to products which are formed in the process of fermentation, and the oxaluria and indicanuria are diagnostic adjuncts in the determination of putrefaction. The author finally makes a plea for more careful and extensive investigation in the study of oxaluria and indicanuria. [F. J. K.]

10.—Fairchild completes the history of a case of neuritis of the median nerve resulting from cicatricial pressure from a wound of the thumb. This case was reported when five operations had been performed, beginning with excision of the cicatrix and ending with amputation of the thumb. Each operation was followed by a temporary cessation of pain but within a few weeks the symptom returned with all its former severity. The pain was so great as to cause the patient to beg to have the arm amputated. It was finally determined to remove the scar in the stump, to liberate the median nerve in its bed, and to surround it with sterilized gold foil. This was done with the most satisfactory result, the patient returning to his work as a bridge carpenter, at which he has continued for the past 18 months. At first exposure to cold or prolonged use of the hand would bring back the pain temporarily, but these returns of pain have gradually and entirely disappeared. [J. H. G.]

11.—Noble describes an operation for cystocele which consists in making a diamond shape denudation of the anterior vaginal wall down to the muscular layer and in bringing this denuded surface together by a number of layers of buried sutures, the principal one being of fine silver wire. The use of this material has never given any bad results in his hands and he prefers it to silk or kangaroo tendon. Catgut is not to be used in this operation except for the superficial suture. The method of introducing the various sutures is explained by a number of illustrations. [J. H. G.]

12.—Individual prophylaxis is discussed by Evans. He confines his remarks to the prophylaxis of bacterial disease. As predisposing causes to bacterial diseases, he mentions mental depression, over-exertion, uncleanness and exposure to cold. He considers in detail the limitations of these predisposing influences, and finally urges that in order to establish personal prophylaxis the resting capacity of the organism should be increased. [F. J. K.]

2. The Comparative Pathology of the Jews. (Concluded). MAURICE FISHBERG.

3. The Pathology of Intrauterine Death. NEIL MacPHRATTER.
4. Rectal Feeding in Throat Diseases. A. C. BARDES.
5. The Medical Aspect of Christian Science. M. M. POLK.

1.—The chemistry of digitalis leaves receives the attention of Joseph W. England, Ph. G. He mentions the fact that various so-called active principles which have been isolated from time to time have been found to be varying mixtures, such, for instance, as the French and German digitalin. According to Schmiedeberg's investigations, digitalin consists for the most part of digitaline, with small proportion of digitin, digitonin and Schmiedeberg's digitalin. It occurs as yellowish white amorphous powder that is soluble in water and in alcohol, but practically insoluble in chloroform and ether. Schmiedeberg decided that the active principles of digitalis leaves were a digitalin digitoxin, digitonin and digitaline. He discovered digitoxin, obtaining it from the leaves. England gives a critical survey of the various investigations upon the subject of the active principles of digitalis. Digitalis seeds are largely used in Germany for the preparation of digitalis principles, hence we do not know very much about the glucosides of digitalis leaves, the main work so far having been done upon preparation of the seed. Discussing the relative value of various principles of digitalis, England concludes, as to digitoxin, that its difficulty of absorption, the length of time necessary to yield cardiac and renal effects, its slowness of elimination and the relative rapidity of absorption of digitalis tinctures, that digitoxin cannot be the most important principle of digitalis leaves. The severe pain follows the hypodermic injection of digitoxin and the injected tissues continue sensitive for a long time. The slowness of the physiological effects indicate a great difficulty of absorption and assimilation. The cumulative action of digitalis has been explained by the fact that the proximate principles of the drug were not excreted by the drug as fast as absorbed, and that they therefore accumulated in the body. But England explains this culminative action to the slow absorption and elimination of digitoxin. [T. L. C.]

2.—Maurice Fishberg concludes his article upon the comparative pathology of the Jews with the following summary: The death-rates of the Jews at all ages are relatively and absolutely lower than those of the people among whom they live. 2. The marriage-rates and birth-rates of the Jews are smaller than those of the Christian. The Jews increase more rapidly in number than those of the non-Jews because they lose by death relatively fewer children and bring more to maturity. 3. The Jews die less often than their neighbors from many of the infectious fevers, particularly epidemic cholera, smallpox and tuberculosis. 4. Syphilis and alcoholism, and also diseases due in a great measure to their poisons, are comparatively rare among the Jews. 5. Most observers have recorded that almost 25 per cent. of all the cases of diabetes occur in Jews. 6. All the functional neuroses, particularly neurasthenia and hysteria occur more frequently among the Jews than others, while all the organic nervous diseases, such as tabes, general paralysis, etc., are less frequent, commensurate with the infrequency of syphilis and alcoholism among them. The great majority of cases of amaurotic idiocy occur in Jewish children, and insanity is met with among Jews between two and five times more often than among Christians. 7. Blindness, color-blindness, trachoma and glaucoma, and also varicose veins, particularly hemorrhoids and hernia, are very frequent among the Jews. 8. All the peculiarities in the comparative pathology of the Jews are not due to any ethnic "bio-static" or racial characteristics of a purely anatomical or physiological nature in relation to non-Jews. They have their origin in the past history of the Jews in their habits of life and in the fact that syphilis and alcoholism have but rarely been seen among them. 9. Where the Jew is commingling with his Christian neighbors and adopts their customs and habits of life sooner or later loses its racial characteristics and its comparative pathology presents no special peculiarities. [T. L. C.]

4.—A. C. Bardes calls attention to the value of rectal feeding in throat diseases. He cites three cases in which it was employed to advantage. One of diphtheria, one of tuberculosis and one of hay-fever and asthma. He sums up the advantages of rectal feeding as follows: The

throat being at rest, is not irritated, struggling in children is obviated, the progress of the disease is shortened, there is no danger of food entering the larynx, the physician is able to give such food and stimulation as he wishes to give, and the food is not bolted as it is when swallowing is painful. [T. L. C.]

5.—Nothing.

MEDICAL RECORD.

April 6, 1901.

1. The Relation of the Public to the Medical Profession. D. B. ST. JOHN ROOSA.
2. The Importance of Aseptic Vaccination, with Remarks on Vaccination in General. WILHELM KARL KUBIN.
3. The Field for Ethyl Chloride Narcosis. MARTIN W. WARE.
1. On the Diagnosis and Prognosis of Diabetes Mellitus. HENRY S. STARR.
- 2.—Wilhelm Karl Kubin discusses the importance of aseptic vaccination, with remarks on vaccination in general. The causes of the various untoward results incidental to vaccination may be enumerated as follows: 1. Impure virus; 2. Abnormal or paradoxical course of the cowpox itself; 3. Improper performance of the act of vaccination; 4. Neglect on the part of the vaccinator to exercise supervision and control the patient until the time of complete healing; 5. Coincident diseases such as scarlatina and measles. He adds a number of cases of untoward complications following vaccination. He concludes by giving his technique for the operation, and recommends that a compulsory national law for vaccination and revaccination should be adopted similar to that of Germany. [T. L. C.]
- 3.—Martin W. Ware studies the field for ethyl chloride narcosis. Physiologically ethyl chloride seems to act on the sympathetic nerves judging from the accelerated pulse, flushing, and the transient dilation of the pupil. Next, it seems to act on the spinal cord and lastly on the brain, but in all of these in rapid sequence. Chemically, being derived from the second series of hydrocarbons it is in the direct line of relative safety of alcohol and ether, derivatives of this group, but since the drug contains one molecule of chlorine and since an anesthetic is dangerous in the proportion to the chlorine it contains, herein lurks a possible danger in ethyl chloride. The writer advocates its use pre-eminently in minor surgery because it is as safe statistically as any of the others; it induces a very rapid narcosis and equally as quick and awakening and is void of any after effects. It is cheaper than nitrous oxide and does away with any especial apparatus. [T. L. C.]
- 4.—Henry S. Starr presents a paper upon the diagnosis and prognosis of diabetes mellitus. Of great prognostic importance are the following features: Age, power of assimilation of carbohydrates; early recognition of the affection; the presence of intercurrent and complicating diseases; condition in life; state of the urine; and the power of absorption of other food stuffs than carbohydrates. He arranges his cases in one of three types from a prognostic standpoint. First, the mild type, to which belong those cases in which the glucose disappears, only after the complete exclusion of carbohydrates, and the severe type in which may be classed those cases in which the glycosuria persists despite the complete exclusion of carbohydrates and even of proteins. [T. C. C.]

MEDICAL NEWS.

April 6, 1901. (Vol. LXXVIII, No. 14)

1. Advertising in the Profession. FRANK LYDSTON.
2. Resection of the Cervical Sympathetic. HOWARD J. WILLIAMS.
3. The Question of Drainage in Appendicitis. A. M. POND.
4. New Methods in Charity, with Better Results and at Less Cost. WILLIAM P. SPRATLING.
- 2.—Williams, in his article on resection of the cervical sympathetic, says that it is indicated in glaucoma simplex, inflammatory glaucoma where iridectomy has failed, hemorrhagic glaucoma early in the disease; and should be tried in absolute glaucoma with pain, in preference to enuclea-

tion. In unilateral trouble the ganglion of the corresponding side should be excised. While the operation may not be curative in every case of glaucoma, the results thus far have been sufficiently satisfactory to make it a desirable procedure in this serious disease. [T. M. T.]

3.—Pond states the inefficiency of attempts at drainage in operations for appendicitis, and says the mere presence of the drain is productive of much harm; it unquestionably produces a hyperemia and congestion of the peritoneum in closest proximity, thereby lessening the absorption by disturbing its normal currents; it also produces adhesions about the drain, which in turn lessens the area of the peritoneum exposed to the infection, thereby limiting its important function of absorption. It is known that the peritoneum is capable of disposing of large quantities of pus under favorable conditions, and chief among these conditions is the equal distribution over the peritoneal area; in order to do this it becomes necessary to use some agent which will put pus and pus-forming elements in solution, and in choosing this agent some very important points to be considered are: 1. Sterility. One species of bacteria is often inert and latent until another species is introduced, thus combining the efforts of both, and a heretofore latent sepsis becomes a rapidly active infection. 2. Power of holding in a homogeneous solution the pus as well as the blood and blood-clots incident to the operation, in order to permit of equal distribution over the peritoneal cavity. The presence of blood-clots in a septic cavity cannot be over-estimated; no richer culture medium is known for bacteria, and these must be protected from invasion. 3. Stimulation of absorption. It is most desirable to remove all septic material as soon as possible, and this is made possible by the power of absorption of the peritoneum, which enormous, namely, from 3 to 8 per cent. of the body weight in one hour. Hot saline solution is very effective and fulfills all the requirements; it can be made sterile into the peritoneal cavity; it possesses the power of putting pus and pus-forming elements, such as blood and blood-clots into solution, thus removing the danger of fresh invasion of infection, and being hot—temperature 105 degrees to 108 degrees F., is a most active stimulant to the peritoneum and its use is unattended by unpleasant sequelae. Increased hepatic activity is another step in the right direction. Such activity produces a detergent influence in all cases of general sepsis, as well as in localized infectious processes, besides removing from the entire physical economy various substances which in themselves would aid, if not produce, septic conditions; this function is certainly worthy of careful study, as it will increase the sources of the surgeon in combating infection, since through the portal circulation we can increase the general resistance against bacteria. Posture does much in these cases; elevation of the foot of the bed a few inches tends to gravitate the fluids towards the diaphragmatic lymph-spaces afford an avenue of rapid absorption of sepsis held in solution. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

April 1.

1. Diseases of the Myocardium. HENRY JACKSON.
3. The Conditions of the Myocardium as Affecting Cardiac Murmurs. H. D. ARNOLD.
4. A Further Note on the Treatment of Epidermoid Cancer. FRANCIS H. WILLIAMS.

1.—Disease of the myocardium does not receive in our text books the important consideration that it deserves, this branch of heart disease being summarily dispatched, while many chapters are written on the accurate differential diagnosis of the various valvular lesions, and this, too, when we know that the diagnosis is not seldom proved to be wrong by the pathologist. Even in the consideration of a case of valvular disease the important points in the treatment and management of the individual case are not. What is the lesion? but, what effect has that lesion produced upon the heart itself? Is hypertrophy or dilation the leading factor in causing enlargement of the heart? Is the action regular, and what is the character of the pulse wave? Heart disease does not necessarily mean valvular disease and murmurs evidently pathognomonic of regurgitation do not prove the existence of organic disease of the valve curtains. Pathologically, diseases of the

myocardium may be classified under the following heads:

(1) Disturbance of the circulation; (2) inflammatory processes; (3) degeneration; (4) tumors; and (5) hypertrophy and dilation. The causes of enlargement of the heart may lie within the heart itself, or outside of the heart. The causes outside the heart may be: (1) pericardial adhesions, especially alcohol; (5) overwork, the so-called soldier's heart, (6) a few cases in which the etiology is obscure; and (7) by far the most important, arteriosclerosis, arteriocalillary fibrosis. In 100 autopsies in cases of cardiac disease, Jackson found a record of 32 cases dependent upon arteriosclerosis, and in only 4 was the weight of the heart under 400 grams. The heart was enlarged in 16 cases. In 6 cases the area of heart dullness was described as normal. In many of the cases the action was weak and the heart markedly irregular and intermittent. The pulse was usually weak, rapid, intermittent and irregular. Murmurs were detected in 10 of the cases, and in 7 of these the murmur was that of mitral regurgitation, but in none was a pathological condition explanatory of the cause of the murmur found, postmortem. In one case there was a systolic murmur in the aortic area. In two cases, a double murmur was heard at the aortic area, and postmortem, the aortic valves were demonstrated to be relatively insufficient. As murmurs indicative of imperfect closure of the valves were heard in 1-3 of the cases of arteriosclerosis, it is evident that the presence of such murmurs cannot be offered as evidence of structural lesions of the valves. In 16 of the cases, a trace of albumin was found in the urine, with casts. In 14 cases there was structural disease of the kidney [J.M.S.]

2.—It has been demonstrated experimentally that when fluid, confined in chambers or tubes, passes through an opening into a wider space beyond, the particles of the fluid are thrown into vibration beyond the opening; and, if the force of the current is sufficiently strong, these vibrations attain an intensity that enables them to be transmitted to the ear, where they become audible as sound. To this sound we give the name murmur. A narrowing of any valvular orifice presents this condition for the blood in its onward progress. A leakage through any of the valves furnishes the condition in a reverse direction. In the aortic area a widening of the aorta beyond the orifice furnishes the necessary condition, even if the aortic valve is normal. Arnold believes that the dilation of the aorta accompanying arteriosclerotic changes, rather than the roughening of the lining of the valve and the bloodvessel, accounts for the frequency of the aortic systolic murmur beyond middle life, a murmur which is so seldom explained at the autopsy by a true stenosis of the aortic valve. Regurgitant murmurs may be caused at any of the valve orifices without disease of the valve itself, provided the orifice is sufficiently dilated to prevent the proper opposition of the valve curtains. Variations in the intensity of a given murmur from time to time may give us information of the greatest value in estimating the condition of the heart. They are to a certain extent a measure of changes in the strength of the cardiac muscle. If with rest and treatment, a weak dilated heart develops a murmur that was not audible before, or if a faint murmur becomes louder, it is a favorable sign, for it means stronger heart action and implies the beginning of compensatory hypertrophy. The diminution or disappearance of a murmur may, on the one hand, mean improvement through the removal of the condition causing the murmur, but it may, on the other hand, mean a weakening of the cardiac power. Even organic murmurs sometimes disappear. If there is good reason to decide that a given murmur indicates an organic valve lesion, do not give too favorable a prognosis simply because the murmur disappears, and do not conclude that the diagnosis was necessarily wrong. Mitral murmurs are much more liable to variation and disappearance than are aortic murmurs. Of all cardiac murmurs, the presystolic murmur of mitral stenosis is the most variable. Yet once definitely heard, it indicates more surely than any other murmur an incurable lesion. A weakened action of the cardiac muscle which failed to narrow the mitral orifice sufficiently, or a weakened action of the papillary muscles failing to hold the valve curtain firmly, may be a sufficient cause for mitral regurgitation. Mitral regurgitation, in debilitated or in dilated hearts may be entirely curable if the cause is curable, though the question depends also on the myocardium and its capabilities. A toxic state of the

blood, fever, and general prostration. Many of the systolic apex murmurs heard in rheumatism are due to the muscular weakness and relaxation from a toxic state of the blood, fever, and general prostration and not to endocarditis. Systolic apex in rheumatism are not necessarily due to endocarditis. They do mean mitral regurgitation, but not necessarily a diseased valve. The so-called functional murmurs on the left of the heart are really due to mitral regurgitation, showing various areas of distribution according to the means by which the vibrations travel from the left auricle to the surface. Whatever their cause, the important thing to understand is the state of the myocardium. [J. M. S.]

3.—Williams prints 3 photographs of a patient who was treated for epidermoid carcinoma of the lip by X-rays. The exposure to the rays lasted 5 minutes and was given nearly every day for some weeks. Experience has suggested that so long a period of treatment is unnecessary. At the close of the treatment of this patient the induration had disappeared; the lip where the growth had been was without a scar and perfectly smooth and soft; and, except a little increase in width on the affected side, there was nothing abnormal in its appearance. Later, this increase in width diminished so that the cosmetic result was perfectly satisfactory. [J. M. S.]

5.—Frank Billings, of Chicago, reports a case of Carcinoma of the pylorus which was secondary to round ulcer. Perforation occurred, the operation of resection of the pylorus was performed and recovery followed. The writer believes that Zeuker is probably correct in his statement that most cases of cancer of the stomach originate from an ulcer base. The patient was a shoe laster of 28 years and married. A paternal uncle died of "tumor" of the abdomen; otherwise the family history was negative. For three years he suffered with attacks of indigestion characterized by epigastric fullness, sense of weight, bloating of the abdomen eructations of gas and constipation. The attacks became more frequent and epigastric pain experienced after a full meal. Gradually the typical symptoms of gastric carcinoma appeared. A diagnosis of pyloric stenosis from gastric ulcer was made. The operation was performed by Dr. Bevan. A tumor-like mass occupied the pylorus, and a perforation had occurred in the anterior aspect of the pylorus. A mass of about three inches long was removed. The duodenal and gastric stumps were closed and then a gastrerenterostomy was performed with a Murphy's button. A microscopic examination of the growth revealed histologically a typical scirrhous carcinoma. An immediate improvement followed the opera-

tion and this continued for some seven months, when the patient began to fail. Nodules can now be felt in the liver and there is every evidence of carcinoma of other abdominal organs. It is of interest to note in this case that the age of the patient is only 28 years, as well as the presence of much HCL in the stomach contents two hours after a small amount of milk was taken. The perforation of the stomach with an opening the size of an ordinary lead pencil caused but little discomfort, and only slight constitutional disturbance for eight hours. [T. C. L.]

6.—E. E. Montgomery treats of puerperal sepsis, its prevention and methods of treatment. Among the important preventive measures cleanliness stands first. If previous infectious disease of the vagina is suspected the part should be surgically clean and a pad wet with sublimate solution should be kept over the vulva. The importance of sterilization of the hands is emphasized. Digital examination during the course of labor must be done most cautiously, and the labor should be conducted in such a manner as to secure the least possible injury to the parts. Instrumental interference is permissible when it is evident that the patient is not able to complete the work unaided. Labor should be terminated by the entire removal of placenta and secondines. Contraction of the uterus must be secured to avoid the retention of clots. The vagina and vulva should be carefully examined for injuries and lacerations, which should be immediately repaired with chromicized cat-gut suture. Occasionally it may be necessary to insert sutures in the cervix to control bleeding. It is essential to impress on the nurse the importance of the most rigid antisepsis. The treatment of sepsis may be summarized as follows: 1. Prevention by the exercise of the most careful asepsis and antisepsis. 2. The accurate examination of each puerperal case to recognize the cause of high temperature and eliminate other factors than sepsis. 3. The maintenance of the vital forces and the promotion of elimination by the administration of diet and remedies to meet indications. 4. The employment of serum injection when streptococcic infection can be recognized or justifiable in pure sepsis. Peritonitis or localized cellular inflammation in the pelvis should indicate vaginal incision in drainage. Hysterectomy is indicated whenever the uterus can be recognized as the seat of localized collections. When the ovary or tube only is involved it should be removed. The recognition of a pus collection demands its evacuation or the extirpation of the organ in which it is situated. 6. The continuance of symptoms of sepsis when local manifestations are not recognized will require incision to determine the presence of secondary sources of infection. [T. L. C.]

7.—William Keiller discusses the anatomy of the renal vessels and pelvis of the kidney in relation to digital exploration of that organ in the operation of nephrotomy. The writer has been astonished that the surgeon who boldly punctures the organ with the needle in the hope of striking a stone, or makes an incision in the convex border and explores the whole pelvis of the kidney that only venous hemorrhage is encountered. Keiller presents an accurate account of the blood-vessel supply of the kidney and from his anatomical study suggests the following technique for the operation of nephrotomy: The kidney is carefully steadied in the dorsal wound and the entire surface of the organ palpated. Then the pelvis may be examined by introducing a finger along the pelvis into the renal sinus, remembering that a large artery lies in the way. If the stone is not found there is to be remembered that the more expanded infundibula are on the upper and lower ends of the organ. These ends and finally the center may be explored with a needle. Should a stone be found, an incision along the convex border would be the safer route to it, unless it is very near the surface when an incision radiating toward the hilum may be preferable. Failing to find a stone by puncture, a vertical incision one inch long and three-quarters of an inch deep should be made made into the convex border of the kidney, the finger introduced and gently pushed on. It will then lie in the connective tissue of the renal sinus and may be dorsal or ventral to the pelvis. The middle, lower and upper infundibula also should be examined in the order named, avoiding as much as possible splitting the ends of the organ, as at either end there is a good deal of interlacing of large vessels. The free venous hemorrhage will follow the withdrawal of the exploring finger, but this

may be readily controlled by pressure of the supporting fingers and subsequently by deeply buried cat-gut sutures through the parenchyma. As considerable damage will be done at least to one infundibulum the lumbar wound should be packed as urine may leak out, and an enormous amount of hemorrhage may be concealed should the wound be closed. [T. L. C.]

8.—B. W. Goldborough and T. C. Cullen report a case of **extrauterine pregnancy of rare form**. The patient was seen on February 28, 1901. She had missed her period in April 1900 and had since then presented the usual signs of pregnancy. In August while lifting some boxes something suddenly gave way in her left side. This occasioned severe pain and she was obliged to remain in bed until November 1st. About the middle of September there was a bloody uterine discharge and accompanying it was considerable pain and nausea. Subsequently she had several discharges which may have been menstrual periods. She was able to be out of bed during the month of November but had to return in December. On examining the patient under anesthesia the abdomen was seen to be very prominent. There was, however, no bulging in the flanks. The umbilicus was converted into a tumor, fully 5 cm. long by 3 cm. broad. The skin over this appeared to be much thinned out at one point which had given way. From this abraded area an offensive chocolate-colored fluid was escaping. Around the umbilicus the tissue is markedly indurated and pits on pressure. Vaginal examination reveals the cervix to be intact, but it is impossible to outline the uterus. An incision was made just below the sternum and continued almost down to the pubes. The abdominal cavity proper was not exposed. Filling the cavity was a large quantity of chocolate-colored fluid. A fetus between six and seven months and a large placenta was found. The placenta was attached low down in the pelvis, was exceedingly friable, but came away without producing any hemorrhage. The walls of the sac were about 4mm. in thickness and exceedingly friable. It is probable that the uterus ruptured and that the fetus with its membranes intact escaped into the abdominal cavity. The fetal membranes were attached to the abdominal wall and to the rounding structure. The large sack was thoroughly washed out with salt solution and loosely packed with iodoform gauze, which was removed on the seventh day, and a light gauze drain was inserted. The upper half of the incision was closed, the lower half left open to insure thorough drainage. On histological examination the placenta was found to be completely necrotic, which accounts for the ease with which it was peeled off and also for the absence of hemorrhage during its removal. [T. L. C.]

9.—C. F. MacDonald presents a paper upon the **early diagnosis of Insanity**, with a discussion of some of the questions which the diagnosis and treatment of the condition inspires. He points out that the significant diagnostic factor to be sought for in the early stage of the disease is evidence of the change in the mental characteristics of the individual, especially if he is descended from insane or neurotic stock. Prominent among the premonitory symptoms of insanity are disturbances of the bodily functions, morbid emotional manifestations and alterations in the mental characteristics of the individual. Especially to be observed are **pavor nocturnus**, insomnia, headache, tinnitus, vertigo, clammy extremities, and other vasomotor disturbances, anorexia, indigestion, constipation, etc.

These are by no means to be regarded as pathognomonic, nor singly, perhaps, even diagnostic, of mental disease. If the tendency is to mental exaltation, or mania, the emotional changes usually take the form of unnatural buoyancy, loquacity, the patient frequently appearing to be unnaturally bright. On the other hand, if the tendency is to depression or melancholia, there are gloomy forebodings, morbid introspections, suspicions, etc. Marked alterations of character are seldom wanting in this stage of the disease. In the diagnosis of insanity it is important to take into account certain negative symptoms, as reticence, obstinacy, sullenness or stupidity, any of which may be significant, especially if such a condition is not natural to the individual. Note should also be taken of the facial expression, the expression of the eyes, the hand-writing, condition of the reflexes, etc., any of which may in themselves be indicative of certain forms of mental diseases. The pulse and temperature should also be observed, as

persons laboring under delirium of fever meningitis, etc. have occasionally been committed to institutions for the insane through inattention to these points. [T. L. C.]

5. On the Relation of the Cerebellum to Multiple Sclerosis. ADLER.

1.—Will be abstracted when completed.

2.—The nature of the brief report is practically fully indicated by the title. It was impossible to state what relation the bacilli had to the disease. They were found but once, but at that time they were much more numerous than all other forms of bacteria, and this fact, together with their disappearance as the disease grew better, and the fact that the intestine is the usual portal of entry in animals, make it seem probable that they had an etiological relation to the disease. Whether there is any general importance in the observation is uncertain. A similar case was investigated for the same bacilli, but they were not found. The case, however, is evidence that these bacilli may grow in enormous numbers in the human intestine. And since the bacillus is known by recent work to be able to cause infection in man, it must be considered highly probable that the organism is by no means one that is without importance in human pathology. [D. L. E.]

3.—The remarkable point in the case reported was that the patient took 2 grm. of corrosive sublimate in solution and yet recovered in spite of the appearance of very grave symptoms. V. Jaksch puts the fatal dose at 0.2 grm. The probable reasons for the happy issue were the almost immediate onset of vomiting, and the energetic gastric lavage undertaken in the treatment of the case. The case is, however, an illustration of the fact that one should not state an absolutely unfavorable prognosis even when a very large dose has been taken. The patient showed very severe symptoms, consisting of severe stomatitis with secondary purulent parotitis, violent gastritis, with bloody vomit, a severe degree of enteritis and colitis with bloody and mucous stools, severe nephritis, and general prostration. All these symptoms gradually disappeared, and the patient regained what appeared to be entire health. The drug was taken on the 22nd of October, and the patient was discharged well on the 16th of December. An interesting observation was the fact that there was a marked skin eruption which appeared first on the 3rd of November, and was of a bright red punctiform character, appearing at first on the hands, arms and chest, and spreading from these points over the surface. It covered the face as well as the trunk. There was no desquamation. The eruption resembled greatly the cholera exanthem, and since cholera in the Hamburg epidemic was treated with large doses of calomel, Krause is inclined to suspect that at least a portion of the so-called cholera eruptions observed in this epidemic were due to mercury rather than to the cholera itself. Krause also notes that the patient had been treated a year before for incipient tuberculosis which had apparently entirely healed in spite of the extreme reduction of his general health immediately after the poisoning. There was no tendency on the part of the tuberculosis to light up the advance. [D. L. E.]

4.—Nothing.

5.—Adler refers to the fact that Ferrier noted that removal of the cerebellum caused movements of the typical disseminated sclerosis type on volitional exertion, and that in cases of atrophy of the cerebellum in man ataxic movements are observed, and that these are sometimes much like intention tremor. Nystagmus and scanning speech have also been noted in cases of atrophy of the cerebellum, hence most important symptoms of multiple sclerosis are seen when there is loss of the cerebellar function. Also the gait in multiple sclerosis not infrequently reminds one of the typical cerebellar gait. He

believes that intention tremor, scanning speech, and nystagmus in multiple sclerosis are all explainable through loss of cerebellar control of volitional movements.

1. Further Investigations Concerning the Value of Arloing and Courmont's Serum Reaction for Tuberculosis; and in especial its Value in Tuberculosis of Cattle. A. BECK and LYDIA RABINOWITSCH.
2. A Remarkable Auscultatory Phenomenon in a Suckling, the Origin of Which Could Not be Explained. K. GREGOR.
3. The Radical Operation for Hernia in Children. H. MASS.
4. A Thread Scoliosognost Kurt Tautz.
5. A New and Certain Method for the Demonstration of Diacetic Acid in the Urine. S. LIPLIAWSKY.
6. Treatment of Gangrenous Hernia. W. PETERSEN.
7. Treatment of Pathological Fixations of the Uterus. STEFFECK.

1.—The authors first state that in a recent criticism (abstracted from the *Deutsche Medizin. Wochenblatt*), Arloing and Courmont made statements concerning the work of Beck and Rabinowitsch which were unfair because they were based upon a false reading of their tables; they state that if their tables are re-examined, it will be found that they are not subject to the criticism made. They then refer to the work of a number of other authors on the serum reaction for tuberculosis, all of them expressing themselves unfavorably toward the test. Finally they report a series of investigations of healthy and tuberculous cattle with other affections than tuberculosis. The diagnoses were confirmed by autopsy. The tables which they present seem to show that the reaction was not more frequent in tuberculous animals than in the non-tuberculous, and was in no way a test of the presence of tuberculosis. They hold by their previous conclusion that the reaction is by no means specific for tuberculosis, and consider that it is of no value in diagnosis. They state that their tests were carried out according to the method advised by Arloing and Courmont, and that the cultures they used were obtained from Arloing and Courmont, and that they always used cultures which were only from 12 to 14 days old. [D. L. E.]

2. The phenomenon which aroused Gregor's attention consisted in the observation of a loud systolic murmur of about the same intensity as that heard with acute endocarditis of the mitral valve, the murmur being heard clearly only over the lateral portions of the right half of the thorax; the second pulmonary sound was not accentuated, and over the pulmonary region one heard a distinct first sound, at the base and at the apex pure first and second sounds. The post-mortem examination showed caseous bronchopneumonia in the left lower lobe, and a general miliary tuberculosis of the lungs and other organs. The heart was small, but there was no other acquired or congenital abnormality of the heart or vessels. The explanation of the murmur was not apparent. It was not a pericardial murmur and there was no evidence of a functional insufficiency. A similar observation by Marfan in a child with splenic anemia is referred to as the only instance resembling this one so far on record. [D. L. E.]

3.—The author reports 33 cases operated on in the course of five years. One per cent. of these were in children. He employed the method recommended by Karowski, which consisted of a simple resection of the sac without any plastic closure. The result in all cases was favorable. After observations extending over years, no recurrences were observed. [M. R. D.]

4.—A description of a simply constructed apparatus for the diagnosis of beginning scoliosis. [M. R. D.]

5.—The test is carried out by making a 1 per cent. solution of paramidoacetophenon, adding 2 c. c. of concentrated HCl to increase the solubility; second, a solution of 1 per cent. potassium nitrite; 6 c. c. of the first and 3 c. c. of the second solution are mixed with an equal quantity of urine, a drop of ammonia is added and the mixture is shaken energetically, when a red color appears. One takes from 10 drops to 2 c. c. of this mixture, adds 15 to 20 c. c. of concentrated HCl, 3 c. c. of chloroform, and

2 to 4 drops of ferric chloride solution. The test tube is corked, and is gently inverted repeatedly, and if diacetic acid is present even in very small amounts the chloroform takes a characteristic violet color after a half minute to a minute, while if diacetic acid is absent the color is yellowish or slightly reddish. The color as noted persists, even in the light, for weeks. About 400 pathological urines were investigated, and they reacted only when diacetic acid was present; this test is extremely delicate, showing as little as one part of diacetic acid in 40,000. Drugs, such as the salicylates, and others which interfere with the ordinary diacetic acid test, had no influence upon the test. [D. L. E.]

6.—W. Petersen recommends local anesthesia in these cases and advocates an extensive resection of the diseased portion of the bowel. He recommends Schleich's infiltration method. According to the author the danger of shock and collapse after the operation is obviated as well as a risk of inhalation pneumonia. For the purpose of anastomosis he employs the Murphy button. He emphasizes thorough emptying of the intestines before suturing. [M. R. D.]

7.—Will be abstracted when completed.

March 7, 1901. [XIV Jahrg. No. 10.]

1. Infiltrated Carcinoma of the Bladder. ENGLISCH.
2. Personal Experiments upon the Influence of Food on the Secretion of Acetone. SCHUMAN-LECLERCQ.
3. The Occurrence of Tubercle Bacilli in Vienna Butter and Margarin. MARKL.

1.—While very rare, primary infiltrated cancer can occur in the bladder wall; the diffuse form is especially rare. Englisch quotes three such cases. The infiltrating tumor takes the place of the bladder wall, which becomes thickened. To the palpating hand the bladder feels regular and strikingly hard. It is difficult to localize, by bimanual palpation, or by rectum. Very diffuse infiltration will give the balloon-like signs of an over distended bladder, distinct upon pressure. The introduction of a catheter will not, however, diminish this. The first symptom is frequency of urination. Pain appears early, upon micturition, and may persist afterward. It may also radiate in all directions. The urine is normal, though cystitis may develop later. The cachexia appears late. Its course is slow, with death finally from an affection of the kidneys. The diagnosis is made by the absence of hypertrophy of the prostate, stricture of the urethra, or stone in the bladder. The differential diagnosis from cancer of the prostate is difficult. The treatment will be extirpation of the tumor as soon as it has been diagnosed. If that be impossible, suprapubic cystotomy will alleviate the pain. Englisch gives a description of his case, with the autopsy. He reports a similar case, in which autopsy was not permitted. [M. O.]

2.—Schuman-Leclercq gives tables showing his own experience for 100 days, under many changes of diet. The urine was examined daily, for acetone, by the Messinger-Huppert method; for diacetic acid by Gerhardt's chloride of iron method; for nitrogen by the Kjeldahl method; for total acidity by Lieblein's method; for phosphoric acid by the Neubauer-Malfatti method; and for the ethereal sulphates by Salkowski's method. These experiments show no relation between the amount of nitrogen and acetone in the urine. But albumen or fatty diet caused an increase in the secretion of the acetone. Last year, he used the Schnitzler respiration apparatus to measure the acetone in the breath. This he added to that found in the urine to make the total acetone excreted. After a description of the experiments, with the diets used, he concludes that the interchange of fats in the body is probably the essential cause, if not the only one of the secretion of acetone, whether from the destruction of the body-fat or the fat ingested, from hunger, fatty diet, pure meat diet, etc., and that the carbohydrates, by their great influence upon the assimilation of fat, prevent the production of acetone by using up the fat. [M. O.]

3.—The presence of virulent tubercle bacilli in ordinary butter and margarin has been proved during the last five years. Inoculations and inunctions of butter have produced both true and pseudo-tuberculosis in animals. Markl used the Obermueller method, inoculating centrifugated butter. Out of 45 cases inoculated, not one died with true tuber-

culosis, and only one with pseudo-tuberculosis. Only ten animals died with peritonitis. None of those injected with margarin died with peritonitis. Markl describes the pathogenic micro-organism in his pseudo-tubercular case. It is a relatively acid bacillus, taking Gram's stain. He considers it a cause of pseudo-tuberculosis, beside Petri and Hermann-Morgenroth bacilli. [M. O.]

1. On the Question of Disease of the Cerebellum. P. I. SHATILOW.
2. On the Affection of the Upper Respiratory Passages in Rheumatism. E. B. BLUMENAU.
3. On the Physiology and Pathology of the Ventricular Septum. Syphilis of the Septum. M. IA. BREITMAN.
4. Secretion of Watery Fluid from the Nose (Hydrorrhea nasalis). A. PH. EKKERT.

1.—Will be abstracted when completed

2.—Blumenau inclines to the opinion that in a considerable number of cases acute articular rheumatism may be preceded by a sore throat. Assuming the disease to be infectious, it is reasonable to suppose that the infection may gain entrance by way of the tonsils. In three out of twenty cases of acute articular rheumatism the author could trace a connection between the rheumatism and the angina preceeding it. In one case the rheumatic affection made its appearance four days and in the other one and one-half to two weeks after the sore throat. Three other cases are reported in which the rheumatism was preceded by an acute pharyngitis. The author reports also two cases of rheumatism affecting the crico-arytenoid articulation. In one the disease was primary and limited to that articulation; in the other it was secondary to typhoid fever which was preceded by grippe. An extensive bibliography is given. [A. R.]

3.—Breitman asks the pertinent question; How would the heart act if the septum were removed? Such an experiment has never been and could not be performed, but nature does perform it in cases of syphilitic affections of the ventricular septum. In these only the latter is affected, the ventricular septum. In these only the latter is affected, the rest of the heart remaining intact. If the septum is crippled by gummatous or ulcerative changes no symptoms make their appearance during life, but the person may be carried off by sudden paralysis of the heart. The altered septum prevents the regularity of the contraction of the ventricles, the right being principally affected. However, when the syphilitic changes involve the cardiac ganglia the heart muscle becomes affected, and a train of symptoms denoting cardiac insufficiency may take place during life. A number of observations of various authors are cited by the author who claims the distinction of being the first to call attention to the subject from the physiologic standpoint. [A. R.]

4.—Ekkert reports an interesting case of a woman, single, 39 years old, of a good family history, suffering from a constant flow of a clear watery fluid from the nose. The patient is of a strong physique, well nourished, but somewhat hysterical and neurasthenic. Since childhood she suffered from a catarrhal condition of the nose. At present, she presents evidences of chronic follicular pharyngitis and catarrhal changes in the lungs accompanied by cough and expectoration, mucous and at times purulent in character. Repeated examinations of the sputum failed to reveal the presence of tubercle bacilli. At times she suffers from chills and elevations of temperature, especially in the morning; but while the latter are ameliorated by proper treatment and change of climate, the secretion of the nose is but slightly modified. It goes on all the time, amounting to about 120c.c. in the 24 hours. At night or when the patient is at perfect rest with the head thrown back the flow is diminished considerably, but the least exertion will bring it on almost in a stream. During the past year she gained considerably in weight and improved generally, the nasal affection, however, remaining about the same, despite local treatment and even hypnotic suggestion. Repeated and thorough examinations of the nasal cavity by specialists failed to reveal the cause of the affection. The author cites a number of more or

less similar cases recorded in the medical literature and comes to the conclusion that this affection is similar to hay fever and is probably of a nervous origin. [A. R.]

1. The Surgical Treatment of Ascites in Cirrhosis of the Liver. N. M. BENISOVITCH.
2. Medical Aid to the Workingmen of Some Factories in the Government of Vladimir during the years of 1895 to 1898. M. S. KAMNEV.
3. On the Question of Diseases of the Cerebellum. P. I. SHATILOW.

1.—Benisovitch discusses the mechanism of the compensatory circulation in hepatic cirrhosis and mentions the operation of Talma as indicated in those cases in which the collateral circulation is not sufficiently established to relieve the rapidly increasing ascites. The cases operated on by Talma himself proved fatal. After that the operation was performed by different men in eleven cases, and in seven the results were satisfactory. The author reports two cases in which he resorted to Talma's operation. In one, the patient, twenty-two years old, suffered from cirrhosis of the liver, probably brought about by chronic alcoholism. He gained admission into the City Hospital, where he was tapped twice without any relief from the ascites. Laparotomy was then performed with the same results. He finally came to the author, who made a diagnosis of tuberculosis of the peritoneum and performed laparotomy under Schleich's anesthesia. The peritoneum was found free from disease. The patient improved after the operation, owing to the evacuation of the fluid, but soon after the ascites returned, together with the usual symptoms. The diagnosis having been changed to hepatic cirrhosis and medication affording no relief, Talma's operation was performed. This was followed by a marked improvement in the general condition of the patient. Two months later ascites again developed, six liters of fluid having been removed by tapping. After that the patient felt much stronger and gained in weight. In the second case, the patient, a man fifty-six years old, with a history of chronic alcoholism, was far advanced in the disease when Talma's operation was performed. He felt much better after it for about two weeks, when he commenced to decline rapidly and died within forty-eight hours. A rapid and marked accumulation of fluid took place before his death. After a review of the literature and the experimental data bearing on the subject, the author comes to the conclusion that in Talma's operation we possess a simple and harmless method of treating ascites in hepatic cirrhosis. [A. R.]

3.—Shallow points out the difficulty of diagnosing affections of the cerebellum during life. Our imperfect knowledge of the physiology and pathology of that part of the central nervous system is in a large measure responsible for this difficulty. The various symptoms observed in the cases recorded in literature may be present in other affections, while the most characteristic ones are indicative only of an affection of the brain. On the other hand, no symptoms whatever may make their appearance, this being due to a compensatory physiologic activity of the healthy portion of the cerebellum, if only a part of it is diseased, or the cerebrum, if the entire organ is affected. This fact had been verified by experiments on animals. In the case reported by the author, a boy, 15 years old, presented severe gastro-intestinal disturbance, characterized principally by headache, vomiting, colic and obstinate constipation. The boy was employed in a confectionery shop and indulged freely in sweets which were usually painted red. The symptoms, together with the history of the case, led to a diagnosis of lead-poisoning, and the improvement, for a time, following the use of iodide of potash and hot baths seemed to corroborate the diagnosis. The physical signs, namely, optic neuritis, slow and tense pulse and the drawing in of the abdomen still more completed the picture of chronic plumbism. About two months after admission to the hospital he began to feel worse. The headache increased in intensity, the vomiting was frequent and not accompanied by nausea, he became listless and indifferent, was frequently found laying on his right side with the legs flexed, the knees drawn tightly against the abdomen and

the head thrown well backward. One morning he was found in his usual position, intensely cyanotic and without the least signs of respiration. The heart-sounds, however, could still be perceived. Artificial respiration soon removed the cyanosis and improved the heart's action, but respiration could not be restored. Seven-and-one-half hours of artificial respiration, together with electricity and diffusible stimuli, proved futile, and the heart finally stopped. During the short time the patient showed erection of the penis, the priapism disappearing with the cessation of the heart's action. The autopsy showed the ventricles dilated and filled with clear, transparent serous fluid. On the left cerebellar hemisphere an area of the size of a pigeon's egg was found to be filled with serous fluid. The walls of this cyst were smooth. On the posterior border of the upper surface of this hemisphere a round fleshy growth of the size of a walnut was found, which on subsequent histologic examination proved to be a glioma. A severe enterocolitis was also demonstrated. A chemical examination of the painted cakes showed the absence of lead. In analyzing the most prominent symptoms, the author calls particular attention to the position of the patient. The paralysis of respiration he ascribes to the pressure of the medulla exerted by the accumulation of fluid. The priapism is explained by the action of the carbon dioxide on the genito-spinal center, since recent investigations have relegated to the past the idea that the cerebellum is the seat of the sexual center. [A. R.]

REVUE DE MEDECINE.

March 10, 1901. (21 me. Annee, No. 3.)

1. Hysterie Anesthesia; its Psychic Mechanism. BERNHEIM.
2. Reeducation of the Movements of the Heart by Methodic Exercises. F. LAGRANGE.
3. A Case of Colothypus, Typhoid Fever with the Lesions in the Large Intestines. PH. BOURDILLON.
4. On the Association of Typhoid Fever and Dysentery. P. REMLINGER.
5. The State of the Blood. Hemoleukocytic Formula, in Zona. SAMRAZES and MATHIAS.

1.—Bernheim, after a study of two cases of hysterical anesthesia reaches the following conclusion: (1) Hysterical anesthesia is purely psychic; its characters are those of anesthesia produced by suggestion. (2) It is much more frequent than authors have admitted. It is often developed or is completed artificially by unconscious medical suggestion or imitation. (3) It is always amenable to psychotherapy; but the latter is often difficult on account of the autosuggestive resistance of the subject. (4) It may have an organic origin, peripheral or encephalic vasomotor constriction or paralysis, but the anesthesia being preserved by autosuggestion, the vascular trouble disappears. (5) Organic hemianesthesia of cerebral origin by lesion in the neighborhood of the sensory decussation may survive the lesion and be preserved by autosuggestion. (6) Sensory impressions in psychic anesthesia are collected and impress the consciousness. But the mind, stimulated by the idea of anesthesia, inhibits and effaces the sensation as well as the collection, by forgetting it. [J. M. S.]

2.—Lagrange continues his paper on re-education of the movements of the heart by methodic exercises. The elasticity and contractility of the veins are two factors that act powerfully in the concert of the forces that assure the regularity of the flow of blood. Among the agents of venous constriction certain forms of vibratory passive movement occupy the first place. When the feet of a patient are placed in a mechanical vibrator the patient first experiences a sensation of cold at the same time that the size of his extremities seems to be reduced. Following this, phenomena of vasoconstriction with the inverse subjective sensations succeed. At the end of a minute or two an impression of warmth makes itself felt and the foot retakes its normal size. The contractility of the veins is also brought into activity by passive movements of alternate flexion and extension, raising and lowering, and abduction and adduction. The displacement of the fluid blood is also a factor of importance in the variations of vascular pressure. Violent displacements of the arterial blood and the too sudden passage of this blood into the venous system, however, are the principal causes of grave accidents that affect the heart or the lungs in the

course of certain exercises that are carried to the last degree of energy. The lung by thoracic aspiration is an important factor in the education of the movements of the heart in cases of tachycardiac arrhythmia. [J. M. S.]

3.—Bourdillon reports the case of a woman aged 60 years who died at the end of 34 days after admission to the hospital of a disease which had presented all the symptoms of typhoid fever, and which was said from the beginning to have a grave prognosis on account of the advanced age of the patient and the profound asthenia into which she had fallen. The diagnosis of typhoid fever was undoubted, both from the clinical signs and by the presence of a positive serum reaction. At the autopsy, however, the small intestine was found to be intact throughout its entire length and the large intestine only presented anatomic evidences of the disease. It has been established in a certain manner that the disease was due to a typhoid infection and that it had evolved in the patient without attacking the small intestine. The lesions in the large intestines were those of an ulcerous and necrotic colitis. From the clinical point of view the predominant symptom was an intense diarrhoea which accounted for the asthenic form of the disease and its gravity. [J. M. S.]

4.—Remlinger reports 7 cases in which typhoid fever and dysentery were associated. In 3 of the cases one disease followed the other. In one case dysentery appeared in the course of typhoid fever. In 2 cases the dysentery followed typhoid fever of medium intensity, in one of which there had been a relapse which was quite serious before the development of the second infection. In the seventh case the 2 infections existed simultaneously. [J. M. S.]

5.—Sabrazes and Mathis have studied the condition of the blood in zona. They find there are no marked changes in the number of red corpuscles or in the percentage of hemoglobin; nor do the red blood corpuscles present any recognizable alteration. The white corpuscles are above the normal on the first day of the eruption. This hyperleukocytosis increases until about the third day, then it decreases gradually up to the fifth day. The increase in the number of white cells is due principally to the polymorphonuclear neutrophiles and the eosinophiles. If the contents of the vesicles become purulent the number of leukocytes diminishes, returning to normal or slightly below normal. The loss being made up by the same varieties of cells that constituted the increase. The period of desiccation and desquamation is marked by a second hyperleukocytosis. Sometimes with the eosinophiles in greatest proportion. At the end of about 2 weeks the blood resumes its normal character. In the clear vesicles on the first day of the eruption the fluid was found to contain 79 per cent. of polymorphonuclear neutrophiles, 19 per cent. lymphocytes, 1 per cent. of large mononuclears, while the eosinophiles were very few in number or were completely wanting. During the following days the percentage of polymorphonuclear neutrophiles increases to 96 per cent.; the microorganisms being in pure culture. On the sixth day the contents of the vesicles presented disintegrating polymorphonuclear neutrophilic cells associated with eosinophiles undergoing disintegration. Neutrophilic myelocytes were found once in very small number, 0.2 per cent. in the blood, but they have not been found in the vesicles. [J. M. S.]

Dionin in the Treatment of Nervous Excitement.—Majewsky (*Pratch*, Vol. XXII, No. 6) presented before the Society of Neuropathologists and Psychiatrists at the University of Kasan the results obtained by him with dionin. He employed it in the insane, especially maniacs, in the stage of excitement. Although nineteen cases are reported. The conditions in which this drug was administered were mental excitement accompanied by congestion of the cerebral blood-vessels; also in sexual excitement. It appeared that subcutaneous injections of 0.04-0.05 grms of dionin constricted the blood-vessels and thus relieved the congestion. In some cases the sexual excitement was allayed and the erections diminished. The author considers it a valuable remedy in acute masturbation accompanying transient mental disturbances. The internal use of the drug is not followed by the same powerful effects. [A. R.]

LIGATION OF THE CAROTID ARTERY AS AN OPERATION PRELIMINARY TO RESECTION OF THE SUPERIOR MAXILLA.

By PROFESSOR CARL SCHLATTER.

University of Zurich.

Translated, with Permission of the Author, by Max R. Dinkelspiel

It cannot be denied, even by surgeons adept at operative procedures, that the modern technique employed in resection of the superior maxilla is somewhat unsatisfactory, both on account of the marked accompanying hemorrhages, as well as the great danger from blood aspiration. Excepting the proved inexpedient method of operating with the head lowered, two methods have been employed for obviating the blood aspiration. Either the trachea, after a previously performed tracheotomy, is protected by gauze or a tampon-canula, or, the patient is only partially anesthetized and thus placed in such a reactionary condition that he can spontaneously throw out the blood, that is flowing into the larynx. The first method—the performance of a prophylactic tracheotomy and larynx-tamponade—is less frequently employed, because it is considered a too dangerous procedure for a preliminary operation, and also because it impedes the ejection of disintegrating masses of secretion and mucus. Thus the second method—performing the operation during partial anesthesia—has been introduced as the sanctioned procedure. This manner of operation, if it is to be followed by favorable results, requires a more extensive operative technique than almost any other operation, and above all, rapid, accurate manipulation, which can only be acquired with extensive clinical material; furthermore, a thoroughly versed corps of assistants is essential—all these being requisites that are not at the command of every surgeon. But even in the hands of accomplished operators, the prognosis, on account of the danger from aspiration during and after the operation, has remained a grave one. During the operation, it is the regurgitating non-aseptic blood coming in contact with mucous membrane surfaces that threatens to involve the bronchi and lungs. The fortunately but brief period of time, during which, in spite of the combined efforts of surgeon and patient, the respiratory passages can hardly be kept free from blood, can rarely be evaded. Martens (1) estimated the mortality of 74 total resections of the superior maxilla, performed in the clinic at Goettingen, at 23 or 31 per cent. In 16 cases the cause of death was disease of the respiratory tract. In the clinic of Greifswald 4 out of 18 cases of total resection (22 per cent.) resulted fatally in consequence of the operation. Bryant's (2) statistics of 230 unilateral resections of the superior maxilla show a mortality of 14 per cent. A remarkably small mortality rate, in resection of the superior maxilla, is reported from the clinic of Zurich, where out of 34 total resections but one death, referable to the operation, occurred. Referring to other statistics on this subject, of which I here report a few of the most recent ones, we see that the exceptionally favorable data just mentioned do not correctly express the universally

accepted grave prognosis of the operation. Koenig (3) in the latest addition of his text book still estimates the average mortality of complete resection of the superior maxilla at 30 per cent. The marked hemorrhage occurring during this operation and its dangerous sequels have recently actuated many surgeons to undertake, as a preventative operation, the permanent or temporary ligation of the afferent vessels, the ligation in the latter case being one in continuity. The first report concerning the ligation of the common carotid as a preliminary operation in operative procedures on the head, is reported from the clinic of Prof. C. Reyher in St. Petersburg, where in all cases a double ligation of the artery was performed and the vessel cut between. In order to prevent the apprehended cerebral manifestations which were liable to occur in this operation, pressure was made for eight days, every hour, from 10 to 15 minutes at a time, upon the vessel to be ligated, and after the operation strict attention was paid to the fact that the patient remained in the horizontal posture. Among 27 ligations of the carotid Reyher had but one death. Weljaminev (4), in 1882, in addition to these cases, reports 20 more ligations of the carotid, performed under antiseptic precautions, all of which resulted favorably; these figures—one death among 47 ligations—with the modern treatment of wounds, classifies this operation among the less dangerous ones. In 1882 v. Lesser (5) also performed a ligation of the common carotid, preliminary to a resection of the superior maxilla. First he temporarily ligated the vessel; then, when after some time, there were no manifestations of cerebral disturbance, tight silk ligatures were placed around the carotid. From the clinical history I believe for a reason which I will give later on, that a still movable lymph gland, diseased by metasasis, was situated on the common sheath of the vessel. In the American literature on this subject, Bryant (2) published a report embodying a recommendation for the preliminary ligation of the external carotid artery, and on the other hand condemning the ligation of the common carotid artery unless necessitated under exceptional circumstances. Markedly different, however, from this ligation in continuity, which has remained in vogue, is the preliminary ligation of the carotid artery in resections of the superior maxilla, as first attempted by Senger (6) in 1895, and which has been warmly recommended since that time. The latter ligation consists of a temporary constriction of the exposed carotid, a sort of Esmarch's constriction, which, instead of involving a whole extremity, in this case only effects a temporary compression of a single vessel. Senger (6) has shown by experiments upon animals that with the employment of a small amount of precaution a ligature can be directly applied to the common carotid artery (of dogs and rabbits) from one to three hours without any danger. In the resections of the superior maxilla performed on man Senger (6) has only constricted the external carotid. He states, "the hemorrhage was very slight, only venous, and not to be compared to the hemorrhages occurring without constriction." Recovery followed without reaction and without any manifestations of disease, either of the brain or the carotid. Even before the publication of Senger's case, Schoenborn had some experience at the clinic of Koenigsberg

with the temporary ligation of the larger vessels, and particularly with the carotid. On account of gangrene of the anterior flap which occurred after a hip joint amputation, for which the common iliac artery had been permanently ligated, Schoenborn was induced to have recourse there after to the temporary ligation of the iliac. He has also a few times temporarily ligated the common carotid artery without any bad results to the patient. At the International Congress in Rome, Schoenborn demonstrated an artery compressor, consisting of two parallel steel rods, movable in the direction of their long axes, and which were beak-shaped, thus permitting the temporary constrictions to be accomplished with the least possible damage to the vessel.* Riese (7) reports two other cases of resections of the superior maxilla with preliminary temporary ligation of the common carotid, performed by Schoenborn at the clinic of the University of Wurzburg. In both cases the patients, in consequence of hemorrhages from the malignant tumors had been sinking rapidly, and were in such advanced stages of the disease, that in both operations the cranial cavity was opened, and, in one patient, even in two places. The result of the temporary ligation, resp. compression, was here also a favorable one, the arterial hemorrhage being very slight. This proposition of a preliminary operation seems recently to have been accorded increased recognition. Kocher (8), in his operative teaching, highly recommends the preliminary ligation of the external carotid artery in resection of the superior maxilla, and believes that it makes the operation more cleanly and simpler. I will consider the cases of Konig, Jr. (9), and those of Gallaudet (10) in another place. The opinion of operators concerning the favorable influence of this preliminary operation upon hemorrhage seems to be so unanimous, that I would have considered a reference to my three following cases of preliminary ligation of the carotid as entirely superfluous, had not Pilz (11), in 1868, in his work on the ligation of the common carotid, asserted, that the permanent ligation of the common carotid, asserted that the permanent ligation of the common carotid in operations on tumors had been entirely useless in 13 out of 17 cases. In my three cases, I, as well as the assistants, were absolutely astounded at the slight bleeding. A retrospection of the above quoted observation, where in no case the effects of the preliminary operation were withheld, decidedly refutes Pilz's objection. It is more justifiable to consider whether the danger of the preliminary operation is not of such a degree that it outweighs its usefulness, and whether a thrombus-formation at the point of ligation, and interruption of the blood supply do not seriously endanger the brain. Let us consider the dangers incident to the ligation of the common carotid and first those produced by a permanent ligation. Formerly a ligature-thrombus, a coagulation of blood up to the next lateral twig, was considered as the regular consequence of blood vessel ligations. Baumgarten has shown that in thoroughly healthy persons, in the absence of suppuration, no thrombus results after the ligation, provided the tying of the ligatures is carefully conducted. Although it is to be admitted that at the present

time under aseptic precautions the prognosis of ligation of the carotid has markedly improved, the fact nevertheless remains, that in spite of the excellent collateral circulation with which the brain is provided by means of the vertebral arteries and the Circle of Willis, in many cases paralysis and softening of the brain may arise after the interruption of the blood supply, be it due to a progressive thrombosis (which, however, under an antiseptically performed ligation as a rule does not take place) or to an embolic occlusion. If, for the previously mentioned reasons, we do not take Pilz's extensive statistics into account, whose material, comprising 314 ligations of the carotid, after all mostly dates from the pre-antiseptic period, and if we only take into consideration the figures of Zimmermann (12), whose cases rather date from the time of antiseptic surgery, we are still surprised by figures showing among a mortality of 31 per cent., 26 per cent. characterized by cerebral symptoms, and in 6 per cent. softening of the brain. Riese (7), who continued Pilz's statistics up to 1885, found cerebral involvement 17 times in 73 operations,—25 per cent. More favorable is Albert's (13) criticism, in which he states, that ligation of the common carotid is tolerably well endured by an entirely healthy person. Among the ligations performed for neuralgias, he finds the mortality 3 per cent. Certainly we will not consider the first-mentioned figures as an expression of the most modern prognosis of this ligation, if conducted under aseptic procedures, for it is known that even the common carotid has been ligated on both sides simultaneously, without any disturbances following. But these figures are, nevertheless, plain enough, even if viewed from an optimistic point of view, to dissuade one from an operation, which, simply as an auxiliary procedure, is perhaps followed by a greater mortality than the principal operation itself. The temporary constriction of the common carotid should not be confounded or judged with the permanent ligation of that vessel. As far as injury to the brain is concerned, it is not immaterial whether the blood supply is cut off only for the short time during the operation, or permanently. When the blood stream is cut off for only a brief period, the danger of a direct atrophic softening of the brain is certainly precluded. The difficulty that confronts us in critically selecting a method, is the question, as to whether the temporary constriction predisposes to a formation of thrombi to a more or less degree than the permanent ligation. Konig, Jr., (9) cut the carotid between two ligatures, because he believed that temporary ligation easily causes thrombosis after the opening of the ligatures. On the other hand, it appears from a theoretical point of view, that we can hardly ignore the fact, that a brief ligation performed with the greatest possible protection to the vessel walls, by means of broad rubber bands, or broad pads placed underneath, predisposes considerably less to the formation of thrombi. The vessel wall, especially the intima, is certainly more injured when tightly ligated by a silk thread than by a broad body remaining on it for only a short time, be it a compressor supplied with rubber, or simply a rubber band. The damage which a silk ligature may cause to the wall of an artery is found pictured in a most instructive man-

* An illustration of this compressor can be found in the Deutsche Medicinische Wochenschrift 1896, pp. 68.

ner in the work of Eberth and Schimmelbusch (14) on "Thrombosis." Here the femoral artery of a strong healthy hunting dog was dissected out and tightly ligated in one place by a silk thread. The ligature was removed in a quarter of an hour, and immediately thereon the artery was again filled as in the normal. After the circulation had continued through the vessel for three-quarters of an hour longer, the ligated portion of the vessel was excised and placed in chrom-osmic acid. In the longitudinal sections it was seen that the intima was entirely lacerated, the media crushed, and the contiguous sheath of the adventitia somewhat loosened. A thrombus extending from, the muscular portions separated from adventitia, which in places were heaped together, into the middle of the lumen of the vessel. In Senger's (6) experiments upon animals no changes worth mentioning took place in the arteries after the carotid had been ligated from one to three hours by means of a rubber ligature and broad pads; those animals not killed immediately, subsequently recovered and remained permanently healthy. The results of two experiments by Eberth and Schimmelbusch (14)* and which imitated the process of temporary constriction, coincide with the views of Senger (6). Eberth and Schimmelbusch clamped the jugular veins of two hunting dogs, in several places with a pair of forceps, so that about one-half of the vessel wall was squeezed between the grooves of the forceps. After a few minutes the blood was allowed to again flow through the vessels for ten minutes, before they were excised. The clamped areas were plainly seen as white spots which showed the thin stripes that had been made by the grooves in the forceps. In both cases microscopical examination of hundreds of serial sections showed neither a change in the vessel, nor a thrombus. Even if in these experiments the duration of the compression does not give data of practical value, the impressions of the grooves nevertheless showed a vigorous crushing of the vessel wall. Even in temporary ligations of arteries with silk thread, Zahn, in spite of the injury produced to the vessel wall, could find no thrombus formation at the point of laceration. Eberth and Schimmelbusch (14) also observed thrombus formation after ligations with threads. Where the ligatures were allowed to remain for a longer period of time, they only found a simple plate-thrombus, which quickly healed, and in a few cases in addition to the conglutination of blood-plates, also fibrin; but a permanent interruption of the circulation in consequence of these ligations was not found in any case. These experiments upon animals, in spite of the favorable observations of Zahn, seem rather to induce us to ignore the silk ligature, and to choose as ligature material broad rubber bands or possibly grooved clamps. In this way the greater injury to the intima, as well as a deposition of blood-plates, can probably be avoided. A simple, uncomplicated retardation of the blood stream—even when it gives rise to a deposition of leucocytes or blood-plates on the vessel wall—according to the experiments of Eberth and Schimmelbusch (14), does not cause a thrombus, provided no other complications, such as injuries to the vessel wall, are present. In addition

to the experiments upon animals alluded to, the result of two post-mortem examinations that were performed upon the two last mentioned cases of Schoenborn, who were operated upon while in a very poor condition, and who died shortly after the resection of the superior maxilla, seem to invite preference for this method of ligation. In the first case, the artery was ligated by means of a rubber band over a small rubber block. In Riese's serial sections of the carotid, the latter was seen to be everywhere patulous, the coats of the artery entirely normal, the endothelium being preserved and nowhere injured. And yet in this case it is surprising, that, in spite of no damage to the vessel wall, there should have been entirely a flat mural thrombus at the upper portion of the area embraced by the ligature, consisting principally of fine fibrin threads and occupying about 1-5 of the circumference of the inner wall. In the second case, the carotid was also patulous at the point of ligation; no microscopical examination was made. In two experiments upon animals performed by Riese (7), after compression of the iliac artery for one hour, obstructive thrombi were found six days thereafter; this, however, is not considered conclusive even by that experimenter himself, as the wound did not heal in an aseptic manner. He also believes that these experiments cannot be considered as conclusive evidence against the application of the temporary ligature in man. It appears to me, irrespective of the fact that asepsis is more easily carried out in man than in animals, that the human carotid is more prone to the formation of thrombi and obstructions than the carotid in animals, not only on account of its thicker and more resisting walls, but also on account of its larger lumen. From all these observations, it seems that a temporary broad compression of the common carotid predisposes less to a formation of thrombi than the permanent ligature, and already for this reason the latter is to be preferred. Moreover, temporary interruption of the blood stream is to be preferred, because it obviates direct danger of softening of the brain. Although the danger of thrombus-formation in carefully conducted temporary constrictions of the carotid is a remote one, if we consider the small amount of observations on man that have been favorable throughout, we are still not yet justified to consider this auxiliary operation as being entirely without danger to the brain. The most ideal solution of the problem would be, if we could entirely ignore the question of ligating the common carotid, and would accomplish our purposes by a ligation of the external carotid alone. This ligation might then also be a permanent one, for the temporary interruption of the blood stream in this case would be an aimless procedure. Under aseptic procedure a thrombus extending from the external carotid to the common carotid could hardly be expected. Among the 130 cases of ligation of the external carotid, compiled by Lipps (15) there occurred only two cases in 1882 (Dubrueil and Pozzi), in which a thrombosis extended into the internal carotid, and in which afterwards a diagnosis of embolism in the brain was justifiable. In Dubrueil's patient, aged 65, a hemiplegia occurred, but only on the 24th day after the ligation. The patient died three days thereafter, but an autopsy was not performed. Among 130 operations

*Thrombosis 1888, p. 101

of the external carotid no deleterious results, directly traceable to the ligation, have occurred, with the exception of these two cases, which can still be considered as belonging to the beginning of the antiseptic era; neither were there any premonitory symptoms indicative of an overfilling of the cranium with the blood supplied by the internal carotid, which alone took up the blood from the common carotid. Gallaudet (10), who observed a right-sided paralysis with maniacal conditions following soon after the ligation of the external carotid and in which, as the paralysis decreased, melancholia occurred, believed that on account of the mania the case was one of central narcosis-paralysis. Does the ligation of the external carotid alone suffice to render the whole field of operation in resections of the superior maxilla bloodless? This is a question which has been raised as early as 1840 by Pirogoff. In 1874 Madelung (16) wrote about the variance that existed among surgeons concerning the value of ligating the external carotid and its relation to the ligation of the common carotid. Lipps (15), in a perusal of the literature on this subject, found that in 1893 this old question of Pirogoff had not yet been unanimously answered. Well-known surgeons had ligated the common carotid, and equally well-known ones had censured this procedure, because ligation of the external carotid had sufficed. According to Friedlander (17) ligation of the common carotid is performed in more than one-half of the cases on account of disease in the region of the external carotid. These contradictory opinions concerning ligation of the common and external carotids, and especially as preliminary operations to the resection of the superior maxilla, have up to the present time not yet been cleared up. It appears from an anatomical point of view that in resection of the superior maxilla the incisions are made principally in the region of the internal maxilla artery, which, as is well known, arises from the external carotid. It would appear that, irrespective of the anastomosis, only those branches of the internal carotid in the orbit should then be taken into consideration. I would like to make a short contribution to this question by the report of the three appended cases, in which it will be seen that my experiments were systematically conducted. In the first case, I temporarily ligated the common carotid. In the second case, separately, first the external carotid and then later also the internal carotid, and in the third case, only the external carotid. In the first case, where I had to deal with a young patient, there was a pronounced sarcoma of the whole right superior maxilla, together with the hard palate, as well as a portion of the left superior maxilla. I feared that during the resection I would also be obliged to operate into the area of the internal carotid, and therefore preliminarily ligated the common carotid with rubber tubing. The result was most satisfactory, the hemorrhage being less than that which ordinarily takes place in these resections. There was not the slightest indication of cerebral involvement. There was no recurrence, and the patient to-day is still in the best of health. The second case presented singular features. In this case I wanted to avoid ligating the common carotid, and placed loose ligatures around the external and internal carotid. The rubber ligature around

the internal carotid was applied only in a prophylactic sense, so that in case an insufficient effect was produced by ligating the external carotid, the internal carotid could subsequently also be constricted. As a matter of fact, the effect produced by only ligating the external carotid is a very moderate one—I believe that I saw no greater hemorrhage even in some resections of the superior maxilla performed without ligating the carotid,—but as soon as I likewise tightened the ligature around the internal carotid, the hemorrhage became perceptibly less. It appeared to me that the hemorrhage in the region of the pterygoid process was the one that was principally influenced by this second ligature. It is difficult to explain this observation, as the internal carotid belongs to those blood vessels which rarely are subject to anomalies. Possibly an abnormality in the ascending pharyngeal artery was present. This artery not rarely arises directly from the bifurcation of the common carotid, it may substitute the ascending palatine artery, or the latter frequently arises from the ascending pharyngeal, which, according to many authors, is the normal condition. In my case the pharyngeal and the internal carotid arteries must, according to this, have been ligated together, which is hardly conceivable, as the pharyngeal would have been seen when the sheath was dissected away. It is more probable that one of those rare anomalies was present where the internal carotid gives off supernumerary branches. Quain found this anomaly 9 times in 144 cases. In my third case, by the ligation of the external carotid alone, an entirely satisfactory result was produced.

CASE 1.—G. J., male, aged 35, was admitted August 25, 1897 for sarcoma, involving the whole of the right maxilla and a portion of the left. His father died from carcinoma of the stomach; family history otherwise negative. In childhood the patient had an attack of pleurisy. Ten years ago he acquired syphilis in America and was cured by inunction. Five years ago the patient had enteric fever, but after that was healthy. Six months before admission he noticed a swelling in the angle between the right eye and the nose, which grew very slowly. Four weeks before admission the left cheek became swollen and the hard palate became loosened. The patient had suffered much from toothache during this half year and several teeth were abstracted because the attending physician thought it was a case of abscess of the gums. But as there were no manifestations of suppuration, it was concluded that it was a case of malignant tumor and the patient was referred to a hospital.

Status praesens. Rather large, well built, but emaciated man. Examination of the internal organs showed nothing of note. The right cheek bulged outward. This bulging began at the right nasolabial fold, and crossed the median line about 2 cm. above it, extending to the lid, and laterally to the ear. The right eye was not as much opened as the left. Both eyeballs appeared prominent, though the right one hardly any more than the left. The movements of the eye ball were unimpeded. Breathing through the right nares impossible. Skin on the right cheek more taut than that on the left, but not reddened or infiltrated. There was no disturbance of sensibility. A sweetish but fetid breath was exhaled from the mouth and there was so much secretion of saliva that the patient frequently was obliged to expectorate. The mucosa of the mouth and pharynx was discolored a peculiar bluish red, and in places covered with stringy hyaline mucus. The palate was more reddened than the throat. The tongue was red and covered with a grayish white coating. The remaining teeth were defective. The mucosa of the right upper alveolar process seemed to be hyperplastic and the process itself thickened to twice the size of the left. This thickening extended in front over the median line to the left canine. The overgrown mucosa bled on the slightest touch, as did also that on the right side of the hard palate. The

right upper canine and one incisor were still in place, but could be pulled out by the fingers. Pressure in the region of the right canine caused foul-smelling pus to exude from the alveolus, but only the fold of the mucosa between the cheek and the upper jaw was sensitive to touch. A freely movable lymph gland, the size of a cherry pit, could be felt on the right side under the angle of the jaw.

Operation September 7th. Total resection of the right and partial resection of the left maxilla. Morphine hypodermically and ether anesthesia. The operation was conducted as follows:

Part 1. Extirpation of the submaxillary lymph by means of a 5 cm. incision over the edge of the right mandible; the gland proved to be the seat of carcinomatous degeneration.

Part 2. Temporary ligation of the right common carotid artery as follows: A T shaped incision was made from the opening over the mandible along the anterior border of the sterno-cleido-mastoid muscle as far as the upper portion of the cricoid cartilage, and then continued to the sheath of the carotid. A thin rubber tube was then passed under the carotid by means of an aneurism needle, and tied. No change occurred either in the color of the face or in the radial pulse.

Part 3.—Resection of the right superior maxilla. Langenbeck arch-shaped incision down to the bone, and the tissues freed from the latter. The relatively few bleeding vessels were tied with catgut. The flaps were held back upon the forehead and the eye ball protected by a spatula. After elevating the periosteum a curved needle carrying a Gigli-Hertel wire saw was passed through the orbital fissure into the malar fossa and another one around the jugular process. After quickly sawing through the bone the frontal process of the maxilla was cut through, from the anterior nasal aperture, and finally the hard plate also sawed through with the Hertel saw. The maxilla was now twisted out with bone forceps. The hemorrhage was moderate and chiefly venous. The main vessels were ligated and the rest of the hemorrhage checked with iodoform gauze tampons. The carotid was then released, but little hemorrhage followed.

Part 4. Partial resection of the left superior maxilla. A portion of the alveolar process was chiseled away, beginning from the point corresponding to the first premolar tooth and extending directly upward into the hard palate. A Hertel saw was introduced into the upper portion of the chisel wound, and by sawing upward and inward, the anterior portion of the alveolar process and of the hard palate were sawed away. This caused the antrum of Highmore to be laid open at its greatest diameter. The hemorrhage was now rather severe. Some of the vessels were tied and the remaining hemorrhage checked with gauze tampons, the gauze on both sides being conducted outward through the nares and fastened together in front of the nasal septum.

Part 5. Reunion of the separated soft palate by four silk stitches. This was done because the soft palate appeared to be only edematous, and not the seat of sarcomatous infiltration. The mucosa of the cheek was repaired by silk stitches and the flap restored. The submaxillary incision and that made for the ligation of the carotid were closed without drainage. There was not much alteration in the pulse after the operation and the closure of the lid on the right side was not interfered with. During the operation considerable bloody mucus was ejected by the patient. In the evening there was so little pain that the patient did not want any morphine injected. Evening temperature, 36.9 degrees C; pulse 118.

September 8th. Patient partook freely of food. His condition was very satisfactory, the evening temperature being 37.8 degrees C; and the pulse 124.

September 11th. Dressings changed. No secretion. Some stitches removed.

September 13th. A slight rise of temperature had been observed since the previous day, reaching 38 degrees on the morning of the 13th. Upon removing the tampon from the left antrum of Highmore and also that from the right, considerable pus exuded.

September 15th. Bandage removed from the head. External wounds beautifully united. The evening temperature still 39 degrees, but without great remission. Dullness was obtained on the left side of the thorax, posteriorly and extending downward from the 7th vertebra, as well as decreased fremitus. Upon auscultation over this region,

weakened bronchial breathing and medium sized rales were heard.

September 17th. The dullness extended to the fifth vertebra. Vocal fremitus was now almost imperceptible on the left side. A puncture was made for the purpose of diagnosis, and foul smelling pus obtained. Resection of the eighth rib was immediately performed. Upon opening the pleural cavity about 200 cc. of fetid pus was evacuated. Soft fibrinous masses filled up the cavity, and in the pus there was what was thought to be particles of food. Drainage established by tubes.

September 19th. Morning temperature 37.4 degrees C; When swallowing there was frequently aspiration, deglutition being difficult. The right iodoform gauze tampon was removed.

September 25th. The lower outer quadrant of the cornea appeared hazy; there was pericorneal injection and epiphora. A bichloride of mercury compress (1:5000) was applied to the eye.

October 1st. The corneal lustre was now restored, and the temperature normal. There was still discharge from the pleural cavity, but without fetor.

October 20th. The patient was able to close his right eye perfectly.

November 1st. The patient was permitted to get up.

November 14th. The patient was discharged. There was no recurrence. His speech was scarcely intelligible. There was no recurrence. There was epiphora, and on account of displacement of the eye ball, also diplopia. On November 25th the patient was placed in charge of a dentist, who prepared a prosthesis, which, on account of the poor condition of the teeth, had to be fastened to gold crowns attached to the three teeth which were still remaining. Support was given to the prosthesis by fitting new crowns over the crowns already present. On the prosthesis there was fastened an obturator according to Schilsky and Brugger.

CASE 2. Sch. L., female, aged 57, was admitted September 20th, 1899, for carcinoma of the right maxilla. Family history negative. Two years ago she suffered constant lancinating pains in the right maxilla from the root of a carious tooth. One year previous she noticed a tumor in the right cheek and occlusion of the right nares. The tumor was painful to touch, and was treated with warm compresses, but continued to grow until it interfered with the movement of the lower eyelid. The patient was thin and pale; musculature thin and flabby; panniculus adiposus absent. Temperature 37 C. degrees, pulse 84. Thorax small and irregular; apex beat in the 5th interspace to the left of the mammillary line, but strong broad and irregular. Upon auscultation a distinct systolic murmur of a "scratching" character was heard over all the valves. Chronic myocarditis. The right cheek protruded more than the left. Upon palpating the tumor the latter was found to begin at the lower edge of the orbit extending to the lateral border of the jugular process and downward to the nasal opening. The skin over the tumor was still intact, but thin and hardly movable. The right eye was not opened as widely as the left. Conjunctive of right eye reddened, cornea cloudy both above and below, tension decreased, and no light perception. The tumor itself was as hard as cartilage and nodulated. The hard palate protruded and in places fluctuation could be elicited. The finger could feel a hard projection of the tumor in the right posterior nares ½ cm. above the posterior edge of the soft palate.

Operation September 23rd. Morphine hypodermically and ether anesthesia. Resection of the right maxilla. Temporary ligation of external and internal carotid. An incision was made along the anterior border of the right sterno-cleido-mastoid muscle as far as the upper portion of the cricoid cartilage. The bifurcation of the carotid under the thick jugular vein was exposed. First a rubber ligature was passed around the external carotid and temporarily tightened. Another was passed along the internal carotid, but not tied. A Dieffenbach-Ferguson incision was then made from the inner angle of the right eye over the lower edge of the orbit and laterally along the upper edge of the jugular process; on the other side the incision extended along the edge of the nose to the nasal septum. The lip being divided in the median line, the flap was drawn aside. The hemorrhage was not noticeably decreased. The mucosa of the hard palate, most of which was found to be intact, was dissected back to the median line with the periosteum. While the bones were being sawed a severe

hemorrhage occurred, necessitating the tying of the ligatures around the internal carotid. This had the desired effect. The tumor was then easily sawed away and removed. The tumor was found to be necrotic in the centre and had severely attacked the bones. After securing the blood vessels the ligatures around the internal and external carotid were removed, but very little hemorrhage followed. The flaps of mucosa and periosteum of the hard palate were united with the mucosa on the side of the mouth, thus closing the cavity above. The wound cavity itself was tamponed with iodoform gauze, which was conducted through the right nares. The skin and muscle flap was restored and sewed, and the wound produced by ligating the carotid was closed with interrupted sutures. Microscopical examination of the tumor showed the latter to be a carcinoma, with hyalin degeneration of the reticulum. Convalescence was interrupted and the patient was discharged on November 12th.

CASE 3.—K. E., female, aged 59, was admitted August 22nd, 1900, for carcinoma of the right superior maxilla. Family history was negative. On January, 1900, patient suffered from an attack of influenza; since then the right nares have been occluded. At the same time she has felt an uncomfortable feeling in the right eye with epiphora. On June 15th the patient experienced severe shooting pains through her head which three days later became located in the region of the right eye. Her physician prescribed morphine with quinine and a salve, but without results. One morning a quantity of dark coagulated blood gushed from the nose and mouth, after which the patient felt better, the heavy oppressive feeling of the head being considerably relieved. The symptoms, however, returned, and the patient consulted a second physician, who removed some tumor masses in the right nares, and then employed cauterization until the patient could again breathe through the nares. The pain decreased under this treatment, but a fetid discharge from the right nares followed. The present tumor began in May, 1900, as a small, painful lump the size of a pea. The sight of the right eye had now become poor. The third physician whom the patient consulted referred her to the hospital. The patient was a medium sized woman with somewhat flabby muscles and a fair amount of panniculus adiposus. There was exophthalmos on the right side, and a swelling the size of a hazel nut extending from the inner angle of the right eye into the nose and cheek. The skin over this tumor was injected but could be lifted at the upper portion of the tumor, while below, it had become adherent. The right nares were full of red ulcerated masses, and did not admit a sound; there was a continual discharge of fetid yellow pus. The nasal septum showed some ulceration and was somewhat deviated to the left. The hard and soft palates on the right are red and protruding. The right protruding eyeball was still freely movable and not sensitive to touch; neither was there any increased tension. Sclera normal. Lower eyelid somewhat edematous and slightly reddened. Right ear appears normal.

No swollen lymph glands could be found.

Morphine hypodermically and ether anesthesia.

Operation August 28, 1900. Resection of the right superior maxilla. Ligation of the right external carotid, and extirpation of the right jugular lymphatic gland. A 5 cm. incision was made over the anterior border of the sternocleidomastoid muscle. The muscle was pulled aside, the bulb of the jugular vein was pushed outward, and a hard bubo excised from this region. A Weber incision was then made along the lower edge of the orbit down the side of the nose to the nasal septum and then the upper lip divided. The tissues from this flap were then dissected free from the bone and drawn back. The jugular process was sawn through with a Gigli-Hertel saw, and the frontal process of the maxilla divided by bone forceps. As the mucosa of the hard palate was also diseased it was separated from the soft palate and the entire hard palate sawn through in the median line. The maxilla was then easily removed. There was exceedingly little hemorrhage. After the vessels were tied pus was seen to flow from the frontal and ethmoidal sinuses, and as both cavities showed granulation tissue, they were scraped with a sharp curet. As the lower surface of the eyeball also proved to be involved, it was removed with the diseased eyelid. Some suspicious places on the nasal septum were also cut away. Three strips of iodoform gauze were placed in the wound cavities; one in the frontal sinus, the second in the ethmoidal sinus and a third as a general

tampon. After extirpating the palpebral conjunctiva the surface under the upper lid was freshened, the flaps replaced, and the upper eyelid sewed to the flap. An attempt to sew the mucosa of the cheek to that of the hard palate, on the left side, was only partially successful, as the mucosa tore very easily. The wound in the neck was also tamponed with iodoform gauze and closed. Pathological examination of the tumor showed it to be a carcinoma. Convalescence was uninterrupted and the patient was discharged as cured on October 9th, 1900.

These three cases, however, cannot clear up, by the establishment of a precedent, the old controversy, concerning the feasibility of preliminary ligating the common and external carotids. On the contrary, these cases show that in one case ligating the external carotid will alone suffice, and that in certain cases it is necessary to ligate the common carotid. The latter may have to be performed on account of various abnormalities of the external carotid. The external carotid may be entirely absent, and its various branches come off individually from the common carotid, the latter then continuing as such, or all the branches of the external carotid may arise in a fascicular manner from a common point in the course of the common carotid. In this case the temporal and internal maxillary arteries may arise from a common branch, which in turn again comes off from the internal carotid artery. I desire to call attention to what appears to me to be a decisive fact in favor of the previously recommended exposure of the carotid. The great danger of recurrence, in resections of the upper jaw, is emphasized by many authors. It is reported that 33 out of 47 patients of König (3), that had withstood the operation, died from recurrences. Of 6 operated cases of the clinic in Greifswald that could be pursued, 5 died from recurrences. 23 out of 34 cases of total resections for carcinoma and sarcoma reported from the clinic in Zurich died from recurrences. On the other hand, it has been claimed how remarkably rare it was in this disease to find enlarged lymph glands in the submaxillary region. The explanation of this is obvious, as metastasis occurs through the lymph channels along the internal maxillary and external carotid arteries to the bifurcation of the common carotid; and it is here that the first lymphatic involvement is noticed. Among the few cases of resection performed with a ligation of the carotid, I call attention only to those of Lesser (5), and Schoenborn, as well as my third case, in which entirely accidentally and only upon exposing the carotid, the first lymphatic enlargements were observed. If in this patient a prophylactic ligation of the carotid had not been instituted, the metastasis would have remained undiscovered, and the resection would have been useless from the very beginning. In the operation on mammary carcinoma, modern surgery strictly requires the exposure of the axillary space, even if no enlarged lymphatic glands can be felt externally, so that a propagation of the disease can be prevented early. The execution of this measure is responsible for the modern favorable prognosis in extirpation of mammary carcinoma. Have we not the same conditions and duties to perform in carcinoma of the upper jaw? Certainly, the majority of recurrences begin in the area of operation itself, and not in the cervical glands, but this should not be a cause for the surgeon to overlook and underestimate the metastasis. Either one should oper--

ate with the intention and hope of removing everything that is diseased, or considering the futility of a radical extirpation performed otherwise, had better not operate at all. Local recurrences can only be successfully combatted by early diagnosis and extirpation of the primary focus, in which case, if metastasis has not yet taken place, my indication for exposing the bifurcation may not be applicable. If I am to briefly summarize the observations obtained from my resections of the superior maxilla and from a study of the literature on this subject, they will comprise the following:

1. By the application of a preliminary ligature, the hemorrhage, as well as the danger from blood aspiration, are markedly diminished.

2. This ligation is highly recommendable in all anemic individuals, and in those whose vitality has been lowered from cachexia and hemorrhages, provided they do not suffer from diseases of the blood vessels, particularly arteriosclerosis. Exposing the bifurcation of the carotid in advanced cases is in itself indicated for the purpose of extirpating the lymphatic glands, which in this region, are generally the first attacked by metastasis.

3. In by far the most cases, ligation of the external carotid alone will suffice; the latter should be a permanent ligation. Conducted antiseptically, the procedure is without danger. The ligature can be applied by enlarging above, the incision, which has been made for exposing the bifurcation.

4. In exceptional cases it becomes imperative to ligate the common carotid, which, if done temporarily, seems to be less dangerous than a permanent ligation.

I fear that without further comment I will be misunderstood, that is, will be accused of taking a too optimistic view of the prophylactic ligation of the carotid, I therefore still feel that I will have to call attention to the fact that the limitations of this operation are even greater in actual practice than at first appears. The majority of resections are for carcinoma, and in individuals of advanced age, in whom marked arteriosclerosis may contra indicate a preliminary ligation of larger vessels.

In conclusion, one other question concerning prosthesis. To-day, whereby the astonishing development of prosthetic technique, defects in the palate can be artificially replaced in a most ideal manner, surgery still seems to strive with remarkable endurance to replace by plastic operations the defects in the palate either by bone or by muscle-flaps, and which, after all, can seldom be satisfactorily accomplished. Of course, the natural substitute will always be accorded the superiority over the artificial one, provided it can be accomplished at the time of the operation. But the inferiority of our plastic operations for this purpose, makes it difficult to meet this requirement. Considering the lightness and service of an artificial substitute, it appears to methat many of the plastic results obtained in this direction are hardly any more worth the trouble expended on them. While we are in a position of unequal competition, we will only welcome it, if the dental technicians can assist, or entirely replace us, in such particularly difficult problems.

In my case of double resection of the upper jaw, the demands upon the dentist were considerable.

The superior maxillary prosthesis had to replace the whole of the hard palate on the right side and partially that on the left. In order to support the displaced eyeball and the retraction of the soft palate, the dentist had to place, in front, a Schiltsky obturator.* The result obtained from the artificial prosthesis, which has been worn for over three years without difficulty is an excellent one. The nasal cavity is entirely cut off from the mouth, the imperfect, unintelligible speech has become faultless by means of the obturator, and the annoying diplopia caused by the downward displacement of the eyeball, has disappeared under the employment of the supporting process, on the prosthesis.

THOUGHTS ON THE TREATMENT OF DIABETES MELLITUS, BEING PART OF A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL MARCH 13, 1901.

By JAMES TYSON, M. D.,

Professor of Medicine, University of Pennsylvania Physician to the Hospital.

As is well known, diabetes mellitus is a condition in which the carbo-hydrate food is more or less unused for the production of body heat or energy, more, where all or nearly all of the carbohydrate reappears in the urine as glucose, less where part is normally oxidized. In the early stages the carbohydrates are probably alone concerned. In more advanced degrees even the glucose formed out of proteid foods is only partially consumed, while in the extremest cases even the fixed albumins are seized upon for conversion into glucose, which is still unoxidized and passed away with the urine. It would seem that there is no inability on the part

*A description and illustration of this prosthesis can be found in "Schweizerischen Vierteljahrsschrift fuer Zahnheilkunde" Vol. 10, 1900 No. 1. Stappan, zur Prothesen therapie nach Oberkieferresektionen.

of the economy to produce glucose even out of the proteid food, or, if necessary, from the fixed albumins as well; but the disability lies in the power to use up the sugar in the blood, and in this consists diabetes mellitus. Is it, therefore, surprising that the more serious forms of diabetes are attended by emaciation and loss of strength?

It is usual to look upon this state of affairs as the result either of excessive glucose formation or of deficient oxidation, the former being commonly assigned greater prominence. It has appeared to me that in this respect—the prominence assigned glucose formation—there has been a certain amount of error. What I mean can perhaps be best shown as follows:—A man has been in the habit of ingesting a certain amount of carbohydrate food daily. His urine is free of glucose, and he is without other symptoms of diabetes mellitus. A little later, while consuming the same food containing the same quantity of carbohydrate, he acquires glycosuria and other symptoms of diabetes. Thus without increasing the ingested carbohydrate the glucosuria appears. The natural inference would be not that glucose is produced in greater quantity, but that its metabolism is in some way diminished.

This brings me to the thought I had wished to emphasize—should not our search for curative treatment be directed more than it has been in the past to measures that aid this oxidation? What are the conditions on which the dietetic treatment is based? Carbohydrate food is withdrawn wholly or in part, the latter only when a part can still be oxidized in the ordinary way, the idea being that the increased amount of proteid food taken under these circumstances will make up for the carbohydrate withdrawn. Any tendency to actual cure thus brought about must be because a greater or less arrest of the glycogenic and glyco-destructive offices of the economy may lead to restoration of function. And this may happen in the mildest cases, but in the mildest cases only, because it is these only in which proteid foods and the fixed albumins are untouched.

It appears to me, therefore, that while availing ourselves of the dietetic treatment for its important palliative effect, we should also seek remedies which will increase the oxidation of the glucose thrown into the blood from the liver; for by such oxidation only can glucose be converted into energy and heat. Otherwise it must pass through the economy unappropriated and useless.

Now as to the remedies which stimulate oxidation. Arsenic has long been regarded as a remedy in diabetes mellitus, and with reason, but the difficulty in the way of explaining its good effects has always deterred many from using it. We know now that it increases the number of red blood discs and the quantity of haemoglobin in them, and thus facilitates oxidation, operating in the way the above reasoning suggests. I have had some experience in the use of arsenic, and I think I have learned the method by which to make it most effectual, and that is by the administration of small doses long and uninterruptedly continued, instead of large doses sufficient to produce its toxic effect. It is true of arsenic as of all remedies, that

it is useful chiefly in mild cases. The dose must not exceed three drops three times a day for Fowler's solution, and one-thirtieth grain as often of arsenious acid.

Are there other remedies which have a similar effect? Iron is one of these, and although I am unable to point to any direct result in the use of iron, even in mild cases of diabetes, comparable to that of arsenic, I have never until recently prescribed it with this end in view, and I shall hereafter use it more frequently with this in mind. Certainly, from it, too, effect can only be expected after long continued use. A drawback to the administration of iron may, in certain cases, be its constipating effect, since constipation is always an unfavorable symptom in diabetes, the cases attended with it being serious cases. This also may, however, be obviated by small doses. Peroxide of hydrogen is a remedy which might be expected to be useful for the same purpose, but it is probably decomposed in the stomach and intestines, and does not reach the blood in a shape capable of exerting any oxidizing effect in the blood.

Massage probably operates in the same way, and also exercise. It is commonly conceded that glucose is oxidized in the muscles, and therefore muscular activity must increase such oxidation, and massage probably does the same. Over twenty years ago, Dr. William Richardson, of London, published a *brochure* on the treatment of diabetes in the preface to which he said: "Ten years ago the author of this little book was attacked with diabetes which presented symptoms of a very formidable character." He first treated himself by the ordinary dietetic and medical measures without any effect, and goes on to say: "He has not only cured himself, but also many others who have faithfully and patiently carried out the system he advocates." I do not think Dr. Richardson's book attracted enough attention, and many who saw it have forgotten it. His method includes bathing of the body daily with warm water, using plenty of soap and exposing the body as much as possible to the sun, a soda bath twice a week, and flannel clothing; also walking exercise, in spite of the lassitude and weakness which make this mode of treatment particularly irksome. He further says: "The bath and walking exercise are of peculiar importance in the treatment, so much so, that if either is neglected, but little good will result." I notice, too, that he took the tincture of perchloride of iron and chlorate of potash, the latter also an oxidizing agent. He says that after three months he was free from sugar, and has been so ever since. As is not unreasonable under the circumstances, Dr. Richardson may somewhat exaggerate the value of this treatment, because it was so successful in his own case. On the other hand, it must be admitted that it rests on a thoroughly rational basis.

It is reasonable to suppose, too, that such metabolism is under the control of the nervous system, and while diabetes is not a disease of the nervous system, we have an abundance of conclusive evidence to show a very close association, to wit: an influence of certain nervous lesions in producing the symptoms of diabetes and the occasional marked benefit from iodides in certain forms of syphilitic diabetes together with the rarer instances in which

the bromides have been found useful. Nervous diabetes may be due to the loss of nervous regulation of glucose metabolism. May not the effect of codeine and other derivatives of opium, as well as the less settled effect of the petroleum products, antipyrin, antifebrin, etc., for which the French school still claims efficiency, be due to the influence upon the metabolism of glucose in the distal capillaries of the economy?

At first thought it may appear that pancreatic diabetes, a well-recognized form, lends no support to such a view, or to put it differently, forces to the conclusion that this form of diabetes, at least, is due to increased glucose production. But this is not a necessary conclusion. While it has been settled that pancreas products and pancreatic juice are of no service in the treatment of diabetes, and presumably, therefore, that the absence of this secretion has nothing to do with the presence of this disease, analogy justifies, at least, a possibility that there may be some other internal secretion separated by the pancreas during life and passed into the blood, the presence of which is necessary to the proper metabolism of glucose.

These are crude thoughts thrown out at this time, with the hope that they may suggest others which will lead us ultimately to more definite and satisfactory results in the treatment of this incurable and only partially controllable disease. While the dietic treatment of diabetes will remain for some time longer our chief resource, I feel confident that we must look elsewhere for the complete curative treatment.

THE MEDICAL RELATIONS OF THE PREVAILING FORMS OF FOOD ADULTERATION.

By HENRY LEFFMANN, M. D.

of Philadelphia

The practice of adulteration is as old as the practice of barter and trade, that is as old as human activity, but the scientific study of it is, as with other phases of scientific investigations, largely a development of most recent times. Within the last quarter century or so, methods of adulteration have been developed by scientific investigation. The large manufacturing corporations have been able to secure assistance from chemistry, and hence we have industrial enterprises, such as the manufacture of oleomargarin and glucose that have no other function than that of adulteration, for neither of these is proper substitute for any of the food articles in which or for which they are used.

The volume or extent of food adulterations has been a favorite topic with the newspapers. They have, of course, treated it more or less sensationally, generally more, and have usually mistaken the scientific questions involved, and confused the scientific nomenclature so that essays have almost always a serio-comic character that renders them of no practical value. As a rule the responsibility for such contributions rests on some anonymous reporter or sub-editor or some professional man who seeks to secure advertising through the means of a sensational interview. It is rare that a chemist or physician of reputable standing will allow him-

self to be the means of promulgating error or misrepresentation.

It is, therefore, an unpleasant surprise to note the appearance recently in a newspaper of wide circulation and good standing, of a sensational article purporting to be based upon information derived from a prominent expert on food-analysis. The article is a sort of edited interview, that is, the expert has furnished a lot of detailed information and the newspaper reporter has paragraphed it and sprinkled it with quotation marks and other signs so as to make the text more readable to the average person. There are so many points about this article that deserve unfavorable criticism that I am unwilling to let the worst of them pass unchallenged, and hence present some discussion of the general question as well as of special points.

We are told first that scores of millions of dollars' worth of adulterated food-products are now sold annually, and that the question has been so serious that Congress has become alarmed and has taken the matter in hand. The great extent of adulterations may be admitted, but it is doubtful if any considerable number of members of Congress have concerned themselves about the danger to the public. One form of serious fraud, namely, the sale of butter substitutes, has been going on with the knowledge of every member of Congress for years and but little relief has been even promised. The adulteration of wheat-flour by corn would probably not have been dealt with by Congress if the revenue necessities of the Cuban War had not rendered the selection of the new objects of taxation necessary.

We are next told that a distinction must be drawn between harmless and harmful adulterants, which statement may be passed without dispute, although it is not at first clear what inference is to be given to the distinction, but this is indicated by the next sentence, in which it is said that "Glucose is not at all unwholesome," because it is prepared from Indian corn. Who knows that glucose is not unwholesome? This is a claim that has been passing for years from book to book and pamphlet to pamphlet, and when we attempt to discover the foundation for it we get little satisfaction. It is true, that a good many years ago, some experts connected with the National Academy of Sciences were on a commission, and after giving some little attention to the subject, passed a "resolution" that glucose is not unwholesome, but it is now well known that these gentlemen were not aware of the composition of commercial glucose, owing to the defective method of analysis, and that their inferences were hasty. The general view is that commercial glucose is merely a pre-digested starch, but in fact it is quite different in its nature. It contains bodies that are not found among the products of starch digestion. Ordinary glucose, by which is meant the syrupy forms (the kind that is almost always used for adulteration), contains about 15 per cent. of unfermentable material, which is as yet but little understood even chemically, much less physiologically. In the face of these facts, how can any one assert that glucose is a proper substitute for starch or sugar?

England has had lately an interesting object-lesson in this field. As is now well known, many cases of arsenical poisoning from the use of beer made from arsenical glucose and invert-sugar oc-

curred in a particular district. These cases may be traced to the indifference of the authorities in this very question of food-substitute. It is known to all who understand these subjects that the substitution of glucose and invert-sugar for malt is merely dictated by questions of profit. The indifference of government in this respect (exhibited as much in the United States as in England) is due to the influence of the rich and powerful corporations, i. e., the political and financial "pull." Hence the use of substitutes goes on without notice to the public or without interruption. The introduction of a poisonous malt into beer and ale would have been impossible except under such a concatenation of circumstances as could scarcely occur unnoticed. We must therefore believe that if the English Government had insisted that nothing but malt and hops should enter into the composition of beer and ale and had required brewers under heavy penalties to make returns of material used by them, the cases of disease and death over which the people in certain parts of England are now mourning would not have occurred. This consideration is, of course, independent of the question of the effects of drinking malt liquors. That portion of the public who desire to drink such liquors is entitled to them made in the proper form, and there is no more justification for government conniving at a substitution or adulteration in the field than there was for ancient monarchs debasing coinage.

Another phase of adulteration that has found many apologists in high places is the manufacture of butter substitutes. It has been loudly proclaimed that the process for making oleomargarin was one of the greatest advances in food-chemistry in the nineteenth century, and that the manufacture inures especially to the benefit of the poor man. The truth is that oleomargarin is about as much benefit to the poor man as wild cat bank notes and counterfeit money. In the first place, it is not butter; it does not have the same chemical composition as butter, and no one has knowledge enough of the matter to say that it can fully take the place of butter. Secondly, the poor man never gets the benefit of its economic features. Careful inquiry will show that it reaches the consumer at practically butter prices. It is true that many persons buy oleomargarin knowingly, but they are restaurant and boarding-house keepers, and no reduction in price of meals is made on account of the cheapness of the article furnished. In the ordinary sales of oleomargarin at grocery stores the buyer asks and expects butter, but gets the substitute at a price nearly if not quite that which he would pay for the genuine substance.

Another phase of the food adulteration question is that relating to baking powders. It is true that an English judge has decided that this is not a food, but this technical legal opinion may be here disregarded. Within the last ten years an active war has been going on between the manufacturers of cream of tartar powders on the one hand and the manufacturers of the alum-powders on the other, and many experts have given their opinions. It is impossible to say at present which side has the worst of the argument. No satisfactory evidence has been brought forward to show why alum

should be more injurious than cream of tartar. The probability is that both forms are objectionable. The leavening of dough should be accomplished if needed by the injection of pure carbon dioxid into the mass without the employment of yeast or any chemical.

One result of the agitation concerning food adulterations has been the adoption of stringent laws regarding articles that are of secondary importance and the adulteration of which is not serious. For example, cider-vinegar has been made the subject of stringent enactments in many states. The adulteration consists principally in the use of dilute acetic acid colored with caramel, this substitute article being closely similar to cider-vinegar and capable of fulfilling many of the purposes of the latter. The legislation, although masquerading under the guise of interest in the public health, has been really impelled by a desire to protect the farmer, that is to enable him to secure a better price for his product.

The legislation in regard to butter-colors has its surprising features. Practically all commercial butter is colored. Preparations of annatto and turmeric were at one time much used, but now coal-tar colors are much more largely employed. Attempts have been made to show that these colors are injurious, but the doses given were so large as to be of no value as guides to the effect in small quantities. To administer to a person in one dose a quantity of color that would be sufficient to color all the butter eaten by the person in six months is about as scientific as to attempt to determine the effect of the use of coffee, vinegar or pepper by administering at one dose all the active principle of either of the agents that would be taken in a long time. The theory that if a gram of a substance in one dose makes a person very sick, one milligram will make him one-thousandth that sick, is at variance with all our experience in therapeutics. That this is about what was done by some of the investigators in the field.

It is worth noting that the farmer-influence in many States has secured laws forbidding the coloring of oleomargarin, while no restriction has been placed on coloring butter.

RUPTURED TRAUMATIC ANEURISM OF THE FEMORAL ARTERY DUE TO GUNSHOT WOUND; WITH REPORT OF A CASE *

By WALLACE NEFF, A. M., M. D.

of Washington, D. C.

Formerly Adjunct Professor of Clinical Injury and Surgical Pathology Medical College of Ohio (University of Cincinnati); late Major and Brigade Surgeon U. S. V.; Member of the Southern Surgical and Gynecological Association; Member of the Medical Society of D. C.; Medical and Surgical Society of D. C., etc.

A traumatic aneurism is the result of a blow, gunshot, or any form of injury to the walls of an artery sufficient to produce dilatation, or a complete rupture of its coats. The injury may be so slight as to rupture only the inner coats, producing a fusiform, or sacculated aneurism. There may be a partial or complete division of the continuity of the

*Read before the Medical Society of the District of Columbia, March 20th, 1901.

vessel causing a false aneurism. There may also be a rupture producing the burst variety.

It is always a serious condition, the gravity depending upon the size of the artery, the locality, and the general condition of the patient. The most typical false aneurisms are found in the extremities, especially in the femoral, as wounds of the artery are frequent.

The Diagnosis.—The diagnosis is not difficult owing to the exposed position of the vessel. The chief symptoms are a tumor, a bruit, and pain neuralgic in character, associated with the history of an injury. The diagnosis is sometimes obscured by an abscess, the wound having been inflicted by exposure to air. A femoral aneurism has been mistaken and opened for a psoas abscess. This seems inexcusable, as when any doubt exists, a positive diagnosis can be made by using an aspirating needle.

Treatment.—Many of the forms of treatment which are applicable to other aneurisms, and for which good results are claimed, are contra indicated in traumatic aneurism of the femoral. Diet drugs, acupuncture, galvano-puncture, needling (McEwan's method), compression, digital pressure, introduction of foreign bodies into the aneurismal sac, as fine steel or silver wire, catgut or silk. Sub-cutaneous injections of a solution of gelatine and salt solution, are methods best employed in inoperable aneurisms. Compression, either mechanical or digital, is difficult to carry out, is seldom successful, and often dangerous. The best treatment is ligation. It is applicable in a greater number of cases than any other method, and offers a better prospect of success. The dangers to be guarded against are hemorrhage, gangrene and sepsis. Several different methods have been employed: 1st, Distal ligature; 2d, Proximal ligature; 3rd, Double ligature. The operations of Wardrop and Brasdor, illustrate the distal method; those of Hunter and Anel, the proximal, and that of Autyllus, the double. The latter was introduced during the 4th century, and consisted in ligating above and below the injured portion. The aneurism is then opened and the sac emptied. This operation was practised for several hundred years until the 18th century, when it sank into obscurity, but has recently been revived, and many of the most distinguished surgeons of the present day are its earnest advocates. Excision of the sac is recommended, the arguments in favor of it being, that harmful pressure of the sac upon the adjacent structures is removed, the change of recurrence of the aneurism is lessened, and the probability of gangrene is diminished. Proximal ligation, however, is considered by a great many of the very highest authorities to be the best operation for aneurism of the femoral.

The Statistics.—The "Medical and Surgical History of the War of the Rebellion" (Surgical Vol. II, Part III, by Otis and Huntington, Surgeons U. S. A., p. 8), states that there were 58,702 cases of shot wounds of the soft parts of the lower limbs. As nearly as can be approximated, 26,000 were in the thigh, about 21,000 in the leg, and about 10,000 in the foot. Of this number, only 156 instances of injury of the large blood vessels of the lower ex-

tremity, or 2.6 per cent. per thousand, were reported. In a summary of 127 cases of ligation of the femoral, for hemorrhage unattended by fractures, there were 91 deaths, a mortality rate of 71.7 per cent. (p. 47). There were 74 cases of traumatic aneurism of different arteries, with 23 recoveries, and 51 deaths, a mortality of 68.9 per cent. 42 of the 74 cases were treated by ligation, of which number 13 recovered and 29 died. In 32 cases there was no ligation, with 10 recoveries and 22 deaths. Of the 74 cases only 20 were of the femoral, with 5 recoveries and 15 deaths. In 16 of the 20 ligation was employed, with 5 recoveries and 11 deaths. In 4 cases there was no ligation, and all died (p. 808). It will thus be seen that there were only 5 cases of traumatic aneurism of the femoral during the Civil War, in which the patient's life was saved. In the "Medico-Surgical Aspects of the Spanish-American War" (p. 130), Senn reports two cases of traumatic aneurism on the "Relief", one an aneurismal varix (case 23), the other aneurism of the femoral (case 24). Neither was operated on, apparently. One is now on the retired list (case 23). The subsequent history of the other is unknown. In the "Report of the Surgeon General for 1900" (p. 298), two cases are recorded during the year 1899 of ligation of the femoral for flesh wounds, the patient recovering in one case, a Mauser wound, and dying in the other, a Remington wound. In the same report (p. 327) a case is reported of traumatic aneurism of the femoral due to a Mauser wound, received at Tarlac, P. I., Dec. 21st, 1899. The external iliac was ligated (Jan. 3rd, 1900), and four days later the leg was amputated at the hip-joint. Patient recovered. The reports of the Anglo-Boer war are incomplete as yet. So far I have only been able to find a record of one case reported by Deputy Inspector General H. T. Cox, R. N., in the Lancet, London, 1900 (11 p. 1074), an aneurismal varix of the femoral artery and vein, caused by a Mauser bullet. This man was wounded at Graspan, S. A., Nov. 25th, 1899. The femoral artery was tied at the Royal Naval Hospital, Plymouth, Eng., April 10th, 1900. Discharged to duty June 1st, 1900, with full use of limb.

REPORT OF CASE.

The following case occurred in my service at the U. S. General Hospital at Ft. McPherson, Ga., during the Spanish-American war: William H. Buckley, private, Battery A, 6th Artillery. Sent from Ft. Clinch, Florida. I first saw him Aug. 30th, 1898, and found a pulsating tumor on the left femoral in Hunter's Canal, about the size of a duck's egg, with a well-defined bruit. He gave a history of having been shot through both thighs with a 38-cal. bullet, on the 18th of July. The bones were uninjured. He had aestivo-autumnal malaria, which, in addition to the fatigue of the journey, suggested the propriety of a few days' rest and treatment before operating. When I saw him the following morning (Aug. 31st, 1898), the aneurism had burst, there was great edema and extensive extravasation, and the pulsation in the two tibials was hardly perceptible, a condition rendering an immediate operation imperative. I was assisted by Major Fry, U. S. V., and Capt. Flagg, U. S. A. The Anesthetist was Acting Asst. Surgeon Rupert Nor-

ton. There were present Major Blair D. Taylor, Capt. Parviana and Lieut. Schriner, U. S. A., and a number of Acting Assistant Surgeons. An Eschmarch tourniquet was applied, a four or five-inch incision was made, and a proximal ligation made. Several handfuls of blood clots were removed. Before operating, I thought I would tie above and below, and dissect out the sac. The rupture was so complete that the walls of the aneurism came away with the clotted blood. I decided not to prolong the operation by applying a distal ligation, but to depend upon the proximal ligation. The wound was thoroughly cleansed and closed, the limb was enveloped in cotton, and slightly elevated, hot water bottles applied, and continuous heat kept up, a special day and night nurse being detailed for that purpose. Primary union occurred. Collateral circulation was eventually established, and he made a good recovery. His general health improved rapidly, he gained in weight, and his malaria disappeared under appropriate treatment. He went home on a furlough six or seven weeks later. When I last saw him the circulation was excellent, there was no atrophy of the muscles, no impairment of function and nothing but the tell-tale cicatrix to suggest what had occurred. In a letter received from him a few days ago, dated Troy, N. Y., March 1st, 1901, he says: "My leg is in fine shape, and never gave me any trouble to amount to anything. It feels strong and does not bother me. I have never rubbed, or done anything for it since I came home. I am a brick-layer, and work about every day, and am out in all kinds of weather, so I think the leg is all right, with all thanks to you." After a careful search of the reports and records, I was surprised to find that this was the only case of successful ligation of the femoral for traumatic aneurism due to gunshot during the Spanish-American war, or, so far as I have been able to ascertain, in the Philippines, or China, up to the present writing, and it is also one of the very few on record in any war. In looking up the literature on the subject, it appears that while traumatic aneurism of the femoral due to gunshot is not uncommon, ligations are usually followed by gangrene, and subsequent amputations, and that it rarely happens that the limb is saved, particularly when the aneurism is of the ruptured variety. The conclusion seems justifiable, therefore, that while the very heavy mortality during the Civil War was due in a measure to a lack of modern aseptic and antiseptic methods, the chief difficulty was the non-establishment of collateral circulation, and even now with a technique well nigh perfect, the same danger exists.

1730 Connecticut Ave.

MULTIPLE TUMORS OF THE SCIATIC NERVE.

JOHN B. ROBERTS, M. D.

As tumors of the sciatic nerve are comparatively rare the following case is placed on record.

A man, aged 39 years, came under my care on January 22nd, 1901, with the statement that 14 years ago he had first noticed three small tumors about the size of peas on the outside of the left leg near the knee. After an attempt had been made to remove these with a caustic plas-

ter, an incision was made, about six years ago, and three small tumors which were called fatty tumors, were excised. The man said that for the last 14 years he had suffered with pain in the left popliteal region.

About five years ago he observed that there was a lump to be felt deep in the left popliteal space. This tumor has been increasing in size and is painful on pressure. It is for this condition that he applies for treatment. The pain runs up and down the leg from the seat of the tumor, which is a spindle shape mass, apparently about an inch and a half in length. The tumor lies directly in the middle line and is plainly felt when the knee is flexed, so as to relax the tissues of the ham. The pain is continuous and worse at intervals. It sometimes keeps him from walking and he has been unable to work for about six years. He says that there is weakness in the left leg and numbness of the foot. He complains of sweating of the left foot. It is always warmer than the other, and its stocking is frequently saturated with perspiration.

I requested the Resident Physician of the Methodist Hospital, Dr. Charles P. Stahr, who had immediate care of the patient for me, to refer the case for examination to Dr. James Hendrie Lloyd, but unfortunately, Dr. Lloyd was not able to see the patient before the day fixed for operation. There was no question in regard to the diagnosis, which was tumor of the internal popliteal nerve. I regret, however, that a careful study of the nervous phenomena was not made.

On January 28th I made an incision over the tumor and found it to be situated within the internal popliteal nerve, the fibers of which were spread over it. The cut revealed many tumors involving the sciatic nerve and its internal and external popliteal branches. The incision had to be continued upwards to the lower border of the gluteal mass of muscles. The whole length of the sciatic nerve from the sacro-sciatic foramen was studded with tumors, varying in size from an eighth of an inch in diameter to about an inch and a half in diameter. The external popliteal and internal popliteal nerves were also involved. I removed in all about thirty-six of these growths. They were evidently developed from the connective tissue in the nerve trunk, and the nerve fibers were separated by them and spread over their surfaces. The tumors appeared to be fibrous in character, but many of them were wholly or in part of a gelatinous consistence, as though the fibroid tissue had undergone a myxomatous change. The fifteen inch incision, which extended from the buttock to the lower extremity of the popliteal space, was closed with twenty-six catgut sutures and an aseptic dressing applied. The patient had practically no pain after the operation. The wound healed by first intention. No marked numbness of the foot remained, and when discharged from treatment he had good motion in all the toes.

The microscopic examination showed the tumors to be fibromas.

No accurate examination of the areas of anesthesia, and no determination of the electrical reactions of the muscles were made. Some of the nerve fibers were undoubtedly injured in excision of these tumors, though as far as possible, the capsule was split and the nerve fibers separated in a longitudinal direction.

An interesting report of tumors of the sciatic nerve will be found in the 20th Century Practice of Medicine, Volume 11, p. 333. This article, written by Dr. James Hendrie Lloyd, showed me that the condition was rarer than I had previously supposed. It is very much regretted that circumstances prevented me having the benefit of Dr. Lloyd's examination of the case before operation was undertaken. The careful study of the neurological features of the patient would have been valuable, though it would not in any way have influenced the character of the operation.

VENOUS ANGIOMA OF THE FLEXOR MUSCLES OF THE FINGERS.

JOHN B. ROBERTS, M. D.

A man of 24 years was operated upon at the Polyclinic Hospital on February 11, 1901, for a swelling about the middle of the forearm on the palmar surface, which had

recently become the seat of pain. He said that he had injured the arm when he was 12 years of age and that the swelling had been there since that time. According to his statement the growth had slowly enlarged, but had not interfered with work, and had given him no pain until recently. On grasping the forearm and having the patient move his fingers there was a vibratory sensation perceived by the hand of the examiner similar to that observed in tenosynovitis. The elasticity of the swelling resembled that of a tense thecal cyst. The tumor was situated in the middle of the palmar surface of the forearm and was about three inches long and an inch and a half wide. A longitudinal incision through the skin, made under anesthesia, revealed a venous angioma involving the superficial and deep flexors of the fingers. The entire thickness of these muscles was involved, as was shown by carrying the finger beneath the muscles. The venous channels were developed in the muscular masses and were separated by abundant fibrous tissue. The fibrous tissue was so great in amount that rolling the belly of the muscles between the fingers gave the sensation of hard particles within their structure. Examination before operation made me think that the condition was possibly a thecal cyst containing rice-like bodies. This was evidently due to the skin and superficial fascia slipping over the rough surface of the tumor. The rough surface was due to the irregularities produced by the hard fibrous tissue and venous channels which made up the tumor. It was evident that the muscular tissue was riddled with fibrous partitions and venous channels.

The motion of the fingers was perfect. Careful examination of the mass showed that the tumor could not be removed without excising the entire thickness of the muscles for a space of about three inches. As this would have done an irreparable injury to the functions of the hand, the removal of the tumor was abandoned. One or two incisions were made in the mass to see whether it was possible to enucleate it, and a small portion was removed for microscopical examination. Bleeding was very free, but after the application of sutures and a pad the arm was kept elevated and no further hemorrhage occurred. It was believed that the pain from which the patient had recently suffered would be relieved by the incision through the deep fascia which was necessary to expose the tumor.

The wound healed promptly; and the man when seen recently, had good use of his fingers, though they were a little restricted by the fear of pain and the local induration at the seat of the operation done sixteen days ago.

The pathological examination made by Dr. Guthrie McConnell, showed many bundles of voluntary muscle fibres cut transversely. Between these fibres in many places was a large amount of connective tissue.

In one portion of the specimen the muscle, having completely atrophied, had been replaced by fibrous tissue. In this same part were many large blood passages filled with blood.

Many of the muscle fibers were much smaller than normal and their nuclei were no longer visible.

In the regions of the blood vessels were numerous crystals, deep brown in color, apparently derived from the blood.

There was no trace anywhere of malignancy.

DIABETES MELLITUS AS A CELLULAR FAULT.

THOMAS C. ELY, A. M. M. D., *
of Philadelphia

Diabetes mellitus, the excretion of sugary urine, though known to the Greeks and Romans, though observed by the Arabs and the inhabitants of Ancient India, remains to-day, as then, of obscure etiology, of indefinite pathology, although of plain and definite symptoms.

The symptoms are of well known nutritional type, resulting from the daily loss by the genito-urinary route of ounces or pounds of grape sugar which, instead of nourishing or affording energy, escapes in the urine. This waste sugar must either be imperfectly prepared for cellular use and cells cannot, therefore, accept it; or the cell pro-

toplasm itself is faulty, is weak or diseased, and cannot accept a properly prepared article.

The fault must be in the sugar preparation or in the sugar distribution in cell metabolism. In certain instances both may be true. In the former case,—in imperfect elaboration of sugar,—whether due to alimentary imperfections, to impaired functions of the liver, or pancreas and its ferment, or to vasomotor disturbance, the process is more simple and the pathology is more definite and well understood.

It is with the latter only,—Cellular Diabetes,—that this paper is concerned, the fault being neither in the internal excretions or external secretions of the alimentary tract, the liver or the pancreas, nor in the nervous system, and hence must rest in the protoplasm of the cell.

It is therefore suggested that even when the entire sugar mechanism is otherwise perfect, sugar may appear in quantity in the urine on account of its non-acceptance by body cells, due to a fault of their protoplasm. If such may be the case, the etiology of many cases of diabetes is made plainer and the stigma of our lack of knowledge of the pathology of diabetes in all cases becomes more endurable, because the whole problem of cellular metabolism is still beyond definite comprehension.

There seem to be five general reasons for considering diabetes as a fault of cellular protoplasm:

1. A Biologic Reason;
2. An Hereditary Reason;
3. A Reason by Exclusion;
4. Associate Diseases;
5. A Therapeutic Reason.

I. A BIOLOGIC REASON.

Through the aid of biology we are just becoming familiar with cell life; we, however, know little, as yet, of its inherent power. We know that cells form fresh cells, form organs, form tissues—in fact, form the entire organism; the individual parts of the organism have been discovered and also the finer components of these parts, the organs and tissues; it remains for future pathologists and physiologists to study the still finer and elementary constituents, the living cells, so far as they are discoverable. We may prophesy a rich store of cellular knowledge in the future. Investigation will deal less with organs,—particularly in what we term general and nutritional diseases,—and more with cell life and cell activity.

It is to a perversion of these cellular activities, particularly in general nutritional diseases, that we may with profit look for an explanation.

With reference to sugar nutriment, what is true of all other substances is equally true of sugar: that after preparation by the cells of digestion it is assimilable only by a still more delicate and more elaborate change,—a change effected by the tissue cell,—which change we call metabolism.

It is to a perversion of this intricate cellular change in tissues that we may ascribe some forms of diabetes. Almost all cells may be nourished by a form of sugar, and sugar foods are supposed to furnish fuel or maintain animal heat and also to supply energy or force manifested through muscular action, and, therefore sugar may especially supply tissue cells; but what cells are particularly involved is a problem that must be solved by the physiologist. However, no matter which cells are involved, *this fact* must be true of all cells nourished by sugar, that any marked and extensive cellular fault in the *taking up* of the sugar product must illustrate sugar supply over and above cellular demand, and must in time further derange cell-mechanism and leave sugar in the lymph, in the tissues, in the blood and in the urine, as we find it in diabetes. An equally decisive cellular fault in the *throwing off* or elimination of sugar waste would likewise further clog cellular activity and soon leave sugar in the lymph, tissues, blood and urine. Of course a double fault, one of both taking up and throwing off sugar waste, must speedily bring on diabetes.

Whether the fault of cell metabolism be hereditary weakness, lack of oxygen which so hasten disintegration, or lack

*Read in the Medical Section of the College of Physicians, Nov. 12, 1900.

of exercise or other ordinary hygienic cause, the result is no less certain. The fault may very probably be a faulty cell ferment.

Physiology cannot explain metabolism,—those intimate chemical changes in cells upon which nutrition and functions depend, or the cellular power of continually using up and renewing nutritional material. Neither can physiology explain metabolic equilibrium, which is defined as the equality between absorption and assimilation of food and the excretion of effete or end products. Modern physiology does not clearly understand either part of the process—anabolism, *constructive* or synthetic metabolism, or katabolism, *destructive* metabolism. In the metabolism of nitrogen food and of water, as well as in that of sugar, the same must be true and may help to explain some cases of albuminuria and even polyuria; but in this paper we are concerned only with the problem of sugar assimilation, and the more closely we study biology, animal and vegetable, the more plausible becomes the view that diabetes is often due to a fault of cell protoplasm.

From primitive cells without a governing nervous mechanism to the highest type under such control, cells have the power of appropriating certain food material and neglecting all else. This is a well recognized biological law and suggests the conclusion that cells deranged in their power of imbibing sugar by reason of an inherited cellular fault, by weakening or clogging with waste and end products, as in gout, rheumatism, alcoholism and obesity, cannot take up their quota of sugar even if the sugar be properly prepared; and such residual sugar, after filling the natural sugar storehouses of the body, saturates lymph and blood and appears in the urine, in the disease we call diabetes.

II. AN HEREDITARY REASON.

There is an hereditary reason for a cellular protoplasmic fault. According to Continental observers (Tyson) one-fourth, and other authorities (Thompson's Diabetes, p. 633) one-third, of the reported cases of diabetes are hereditary, which suggests a cellular hereditary fault. If we regard heredity as hinging upon the fact that every living cell indicates a mother cell, its matrix, we readily see how a protoplasmic fault in the original cell in acceptance of sugar and disposal of waste is transmitted, and, in the absence of a definite pathology in the organs, diabetes, we may with reason look to the cell for a predisposition present in the earliest cells and transmitted, although not yet recognized. If we regard heredity as the result of the biological law that "each cell or aggregation of bioplasms of which the living body is composed has been developed from a preceding cell and inherits the properties or forces of the parent cell from which it originated," it helps explain hereditary diabetes. We are familiar with the fact that although some cells are sterile and some require special preparation before they can produce a new brood, yet certain cells especially proliferate and *all cells* have their origin in a matrix,—a mother cell,—just as the whole organism originates from a single egg-shell. Each tissue cell of maternal character may be likened to an ovum, and "each tissue bears, as a rule, the stamp of its matrix. It is built on the maternal plan," and if this maternal plan represents a protoplasmic cellular fault as regards the metabolism of sugar, we surely get such in the entire organism,—hereditary diabetes. Although the pathology cannot be found in the organs, we may confidently expect to find it in the cells.

When so large a percentage of diabetes cases are hereditary, if the disease were due to an organ we should expect some successive regularity of hereditary lesion in said organ or organs, but none such occurs. If, on the other hand, the disease be due to a general cellular weakness, our disappointment in not yet finding gross pathological lesions will only be an incentive to more vigorous work in this direction: for the process must be as general as nutrition itself, as incommutable as the number of cells themselves. Though well assured of the fact of sugar metabolism, the physiologic explanation of it is not known, and much less the pathology.

III. A REASON BY EXCLUSION.

There is an argument by exclusion for cellular diabetes. Cells require so much sugar in an assimilable form, and it is the function of certain organs to perform the work of preparation. It is likewise the function of nerve-centers to control, by proper conducting paths, the process of proper

preparation and assimilation. Granted that the work is all properly done, so far as we know, with perfect organs and normal nervous system, and yet we have diabetes; we may fairly by a reason of exclusion look to the purpose of nutrition—to the cells themselves—and conclude the fault may be in the cell protoplasm.

The fact that the disease is differently classified among kidney diseases (no doubt from the urinary phenomena), liver diseases, pancreatic diseases, disorders of the digestive system, or alimentation; disorders of the sympathetic system; and that in diabetes all of these organs may be functionally and physiologically perfect, forces us to look elsewhere for an explanation, and, very naturally, we search in a most likely quarter, the very end of all food, viz: cell life, where, as yet, we cannot expect to find a pathology, for we have no definite cell physiology as a working basis. Saundby affirms that diabetes is steadily and rapidly increasing in all the great cities of Europe. It is called a civilization disease; and when we consider that the people of modern civilization most abuse the digestive functions and cerebro-spinal axis we see why many cases are explained by disease of the alimentary tract or accessory glands, or disease or injury of the nervous system.

We are familiar with alimentary diabetes, with diabetes due to a disturbance of the glycogenic functions of the liver, with pancreatic diabetes, due to interference with its ferment from cancer or from cirrhotic or fatty changes; with nervous diabetes, from disease or injury to the sympathetic or trophic system; and we find a pathology for the same and they are easy to understand, as all these functions are necessary to prepare a proper sugar article for cellular use, and in such cases a healthy cell cannot accept improperly prepared sugar and we may, and often must, find excess of sugar in the blood and urine—the so-called diabetes. When we consider the modest demand made by the cell for fuel and energy, and how lavish its supply; when we consider the large amount of sugar and starch and other foods consumed by the human race, as compared with sugar needs (the supply always exceeds the demand; when we consider how civilized people cook and prepare all these forms of sugar to coax and force them past the intestinal barriers unchallenged or with mild protests, to finally reach the cell doors in enormous and unnecessary amounts; there seems a good reason for damage to cellular mechanism and for a cellular sugar fault among the civilized. The active life of the savage might use up as energy what was not needed for fuel, and the raw food of the savage if taken in excess would early produce Nature's evidences of Nature's protest in intestinal symptoms before appearance of the urinary symptoms of more civilized people.

IV. A REASON OF ASSOCIATE DISEASES.

In diabetes, concomitant, intercurrent and associate diseases point to metabolic disturbances as the basic cause. Its frequent occurrence when metabolism is weakest,—after febrile attacks and after or during acute diseases,—is equally significant. Its frequent association with diseases of well-known cellular weakness—with gout, rheumatism and obesity—is still stronger evidence of faulty metabolism. The close relationship of diabetes with uric acid accumulation points to the cell. According to Coignard Camillon and other French observers, excess of uric acid is often a forerunner of diabetes. In about one-third of diabetes cases there is a history of alcoholism, which strongly suggests cell disintegration.

Ord reports a series of diabetic cases in which gout occurred in one-third and rheumatoid arthritis in others. After the age of fifty gout and glycosuria and diabetes in the presence of obesity may interchange without emaciation or particular debility or seriousness, as if, though with cellular weakness, sufficient cell power yet remained to perform sugar and proteid work, but only indifferently.

That the esquimo can live solely upon fat; the South Sea Islander upon sugar foods the hunter and trapper upon meat, and civilized man upon a conglomerate mixture of all these in varied forms, gives us great respect for all organs which have to do with food-preparations and food-alimentation, and the highest appreciation of those body-cells which have the most delicate and most important work to perform,—that of assimilation.

V. A THERAPEUTIC REASON.

It is worthy of mention that the only drugs which benefit diabetes, arsenic and codein, may be called cellular

/drugs, as they have no particular action upon the liver or pancreas, upon cancer or fatty changes, but have a definite and well recognized action upon general body cells. Arsenic as an alternative, reconstructs, builds up weak cells, as we may observe in general skin diseases other than those associated with diabetes. Opium conserves tissue, retards and prevents waste. Under the judicious use of these cell-drugs, if we may call them, many diabetes cases improve and some get well.

The essential therapeutics, however, is the diet or withdrawal, partially or wholly as the case demands, of the sugar supply, allowing the cells concerned in the assimilation of sugar to recuperate.

This dietetic treatment, so valuable in diabetes, is of little benefit in cancer, cirrhotic change, or fatty degeneration, or even weakness of the sympathetic nervous system. In regard to the derangement of the nervous system as a full explanation of diabetes, granting that it may be a sufficient cause in some instances of shock or traumatism, yet the most unmanageable and serious case of diabetes are those in which there is no explanatory history or demonstrable lesion. However, by derangement of the sympathetic control of the vasomotor system we can explain almost every disease.

Generally speaking, the nervous system controls metabolism, but, aside from nervous control, there is inherent cell power in gradation from the lowest form of cells with no nervous control, to the highest with most delicate and intricate governing mechanism.

Just as in the lowest forms of life cells depend entirely upon inherent cell-power, so in the highest forms in which such inherent cell-power remains it is reasonable to assume additional sympathetic control.

Again, if we argue that organic diseases—for example, of liver and pancreas—are causes, we shall still have to explain the fact that in older people, where such organic changes as cancer and cirrhosis most frequently occur, diabetes, instead of being more deadly, is more amenable to treatment; which quite forces us to look elsewhere than the vital organs.

Again, the fact that diabetes is most fatal in the young may be explained by this cellular theory as the survival of the fittest in cell life. Very weak cells fail utterly in early life. Older cells adapt themselves, become more resitant, and perhaps relegate their work to other cells, just as the sound hemisphere (?) of the cerebrum will imperfectly take up the duties of its injured fellow.

It is interesting to note that the plasma is usually loaded with fat molecules which can be seen in fine particles. If this fat appeared in the urine as it does in the serum we might call the disease diabetes, mellitus lipogenicus. The general presence of this fat is best explained by a theory of metabolism. The fact that examination of the feces and urine shows a striking defect in assimilation of albuminoids and fats is likewise best explained by a cellular fault.

Some practical value of such a theoretical discussion must be its best excuse, and how little can be accomplished by drugs is herein foreshadowed. In uric acid cases moderate doses of Salicylates may assist arsenic and codeia. The most successful treatment is a rest cure or partial rest cure for cell life, withdrawing sugar. The rest must be complete, by a total withdrawal of sugar, if by this means a patient tends to recovery; or a partial rest cure may be indicated when weak cells are found to thrive better on some most assimilable forms of carbohydrates.

Even though some sugar persist in the urine and the patient nevertheless improves in weight, strength and general health, it were better to be content with this result rather than remove both sugar and patient by heroic drug measures or by starvation, to which a too rigid diet sometimes leads.

In conclusion, when we consider the therapeutic reason for the argument of cellular fault, and especially the effect of diet, a reason of associate diseases, the reason by exclusion and that of heredity, we seem to have an explanation of the etiology of this obscure disease worthy of consideration.

And, finally, the strongest of all reasons, the biologic law that applies to cells,—the most primitive as well as the most highly developed,—viz: there is an intrinsic power of imbibing and digesting the necessary and refusing all else.

On the use of Colloids in the Nourishment of Infants.

K. GREGOR.

Gregor reports a series of nitrogen metabolism experiments which he has carried out in animals and in children, in which he determined that gelatin solutions are absorbed, and that the gelatin is used in the organism, and is apparently able to substitute for albumin, fat or carbohydrate in the nourishment. He, however, ends his statement that the use of gelatin had evidently, from a clinical standpoint, an unfavorable effect which consisted chiefly in a tendency to produce inflammatory changes in the intestinal tract. In what way these changes are produced could not be definitely determined. Disease of other organs was not discovered. The use of gelatin in small amounts, however, tended to cause diarrhoea. There have been, he states, no previous records of any satisfactory investigations concerning the use of colloidal substances in the nourishment of infants, either in simple solution or when used in dilute solution, and while his results have been unfavorable from a clinical standpoint, he believes that they have been of value in demonstrating the actual standing of these substances. He directs attention to the fact that fruit gelatins, extract of grapes, and extracts of veal and of calves' bones, are frequently recommended by writers for use in older children, who are emaciated or have poor appetites. Since these substances contain a large amount of colloids, he considers that they should be investigated in a more definite manner than has heretofore been done before their use is recommended. [D. L. E.]

A Contribution to the Study of Disturbances of the Lung Circulation.

J. ESSER.

Esser considers that the width of the vessels in the lung are to a considerable extent controlled by the respiratory movements by means of the elastic fibres which run from the vessel walls to the walls of the alveoli. He discusses disturbances of the respiration in their secondary relation to disturbances of pulmonary circulation under the following headings: First, a disturbance of the excursion of the lungs through pleural adhesions, persistent exudates, or deformities of the thorax. Second, a decrease in the elasticity of the lungs through widespread indurative processes, or emphysema, with ultimate disappearance of the elastic tissue. Third, rigidity of the pulmonary vessels through sclerosis of the vessel walls. These factors are likely to be combined. The first heading includes conditions which have relatively little to do with the point which he wishes to make in this paper: the elastic traction between the alveoli and the smaller vessels is of much less importance under such circumstances than the disturbances of suction action through the interference with proper respiration. As to the second heading, he considers that the elastic traction may play an important role in these conditions in disturbing the lung circulation, and in sclerosis of the vessels of the lungs there is of course more or less complete interference with dilatation of the vessels by means of the traction of the elastic tissue. He is inclined to attribute much of the circulatory disturbances in emphysema to this interference with the traction of the elastic tissue, and the consequent relative increase of the tension in the lungs, which increase ultimately overtakes the right heart. [D. L. E.]

A New physical Sign in Cases of Dilatation of the Stomach.—W. D. Sherwin, *Am. Med. Assoc. J.*, 1900, French, Vol. 22, No. 5.) found that in dilatation of the stomach a dull sound, similar to the one obtained in pleurisy with effusion, may be elicited by percussing the left subcapular region on a level with the lower border of the left lung, in the region of the ninth, tenth and eleventh ribs. The area of dullness is 4 to 5 cm. wide, and is separated from the vertebral column by a small triangular space of much clearer resonance. When the patient bends forward, the dull sound becomes clearer, and on further stooping, it becomes tympanic. After thorough exercise the dullness disappears similarly. The explanation offered is that the dilated and distended stomach raises the diaphragm and presses the lower part of the left lung against the back, rendering it airless. [A. R.]

The Philadelphia Medical Journal

A Weekly Journal Owned and Published by The Philadelphia Medical Publishing Company and Conducted Exclusively in the Interests of the Medical Profession

JAMES HENDRIE LLOYD, A. M., M. D., *Editor-in-Chief*
JULIUS L. SALINGER, M. D., *Associate Editor*
Assistant Editors

\$3.00 PER ANNUM

The New Therapeutic Monthly.—This new Journal, which will enter a most important field of medical journalism, will appear in a few weeks, as we have already announced. We wish to make the additional announcement to our friends that the *Therapeutic Monthly* will be sent to all paid-up subscribers of the *Philadelphia Medical Journal* who make a request for it. Professor James Tyson will have editorial charge, and will have as his associates Dr. T. L. Coley and Dr. T. Mellor Tyson. No efforts will be spared to make the new Journal a thorough representative of therapeutical work and literature, and we believe that the opportunity here mentioned will be appreciated by all our subscribers.

A Voyage in a Disease-Ridden Ship.—Nothing can better show the need of rational ideas on the subject of the infectious diseases than the experience last summer of the steamer *Chile* off the west coast of South America. Her log reads like a page out of the *Inferno*, and all because of the barbarity and ignorance that prevail in respect to the contagious diseases. This steamer left Panama in July, bound south, and when two days out developed yellow fever. From this moment she was a doomed ship, an ocean outcast, a pariah of the deep. From port to port she sailed, begging in vain for succor and Christian charity, but was refused everything because she had a few cases of yellow fever on board. From port after port she was turned adrift; at one place she was even driven out of the harbor by a gunboat. This sort of thing went on until the west coast of South America had been pretty well skirted and the *Chile's* coal bunkers were exhausted. Then, of course, the helpless steamer could proceed by her own power no farther. Gunboats could not drive her away, and it is a wonder that they did not stand off and sink her. The ports that had refused to give her medicines had also refused to give her coal, but the last port had to give her coal in order to get rid of her. So she was towed five miles out to sea, and coal sent to her in an old barge. The *Chile*, with her sick crew, had to unload the coal as best she could, and then sink

the barge. No medicines, disinfectants, or supplies were granted at any port—only maledictions and orders to get out! There was no doctor on board; only an impostor, who claimed to be one. All this time (about six weeks) yellow fever was holding high carnival; men were dying, and a lot of passengers were terrorized, and their lives put in peril. This sounds like some tale of an Ancient Mariner, or like a proceeding in the Middle Ages. It was all because there was no quarantine port on the west coast of South America, and because of the disgraceful panic that assails some communities at the mere mention of the name of yellow fever. How absurd this would all seem if the disease were yet proven to be only propagated by the bite of the mosquito!

The report on International Quarantine, adopted by the Pan-American Medical Congress, in the city of Mexico, 1896, provides, according to the *Public Health Reports*, that each government should maintain quarantine stations at its domestic ports.

Smallpox in the United States.—According to the *Public Health Reports* there has been more smallpox in the United States during this past Fall and Winter than during the corresponding period one year ago. The total number of cases reported up to March 29th was 11,964, as against 7,279 for approximately the same date last year. What we wish to call attention to especially is the astonishingly low death rate. As we pointed out last year in these columns, smallpox has been prevailing in widely separated parts of the United States, but almost everywhere it has presented itself in an exceedingly mild type. Thus there were but 157 deaths among the 11,964 cases—little more than 1 per cent. Some of the results are still more striking when the figures are analyzed. Thus, in Wisconsin 560 cases were reported with only four deaths. In Virginia there were 257 cases without a death; in Tennessee, 308 cases with four deaths, and in Oklahoma Territory 690 cases without a recorded death. In Minnesota there were not less than 1985 cases reported, and yet out of all these cases there were recorded but three deaths. In Colorado there were 1190

cases without a death. In Louisiana the disease appears this year, as last, to have prevailed in a more malignant type than elsewhere, for out of 157 cases there were 37 deaths. This is about 23 per cent. This mortality rate for the whole United States would have given about 2760 deaths instead of the 157 deaths reported. This serves to show, as graphically as figures can, how mild a type of smallpox has been prevailing in the country at large. In the large Eastern States, New York and Pennsylvania, there has been but little smallpox this winter; in the former 416 cases; in the latter only 102. Pennsylvania had but 3 deaths against New York's 67.

We do not know just how accurate all these returns may be, for they are published in the *Health Reports* without comment; but we cannot refrain from commending them to the thoughtful consideration of all persons interested in preventive medicine. These figures certainly lend support to the claim that smallpox has been brought under some sort of control by vaccination. They clearly indicate that from being what it once was (the scourge of the race), smallpox has become, in a large measure, a comparatively harmless disease.

Compulsory Vaccination.—In further proof of the efficacy of vaccination is the experience just reported from Chicago. The right of a school teacher to exclude from a public school a scholar who had not been vaccinated was under discussion in that city, and an appeal to the records of the Municipal Health Department was made in order to prove that vaccination is a true prophylactic. The results were striking. From November, 1900, until April, 1901, the period of the recent epidemic in that city, 171 cases of smallpox had been reported, of which 140 cases were in persons who had never been vaccinated. Of the remaining 31 cases, 29 were in adults who had only imperfect scars, if any at all. Hence, of the 171 cases, only 2 presented marks of successful vaccination. One of these patients was 40 years old, and had not been vaccinated since childhood; the other, 35 years old, had been vaccinated successfully when a child, and unsuccessfully three years ago. One of the Chicago newspapers, which has been investigating the subject, says that the disappearance of smallpox from the public schools of that city has been coincident with the enforcement of the Compulsory Vaccination law. This act went into effect in 1867, and from that date until 1881 there were only 17 cases of smallpox and varioloid in the public schools. The *Public Ledger*, of this city, does a public service in commenting on these facts editorially, and we are obliged to it for the figures quoted. These statements are sufficient answers

to the critics who oppose, and the madmen who resist, vaccination. The Supreme Court in this State sustains the right of a school teacher to exclude an unvaccinated scholar from the public schools.

A Martyr to Duty.—The assassination of Dr. Ralph Erskine Johnston by an insane Italian patient in the State Hospital for the Insane, at Danville, Pa., was another instance of the sacrifice of a valuable life on the altar of professional duty. Such a man deserves public recognition for his worth and martyrdom, and we publish elsewhere a detailed sketch of his useful career. Even in these days of military ardor and showy pride over deeds done on the field of battle, this truly heroic death will not lose in lustre and force of example by comparison with the fall of any of the bravest men in the campaigns of Cuba, China or the Philippines. The saddest reflection of all, after our first outrush of sympathy to the stricken wife and sorrowing friends, is that such frightful catastrophes may still continue to happen, as they have too often happened in the past, in the arduous and responsible lives of the unselfish men who are devoting themselves to the care of the insane. Let this mournful event remind us all, in our fraternal sympathy, that the men who are working in the asylums for the amelioration of the insane, are often among the best and most self-sacrificing in the ranks of our profession.

Notes by Kitasato on Plague in Japan.—Dr. M. J. Rosenau, of the U. S. Marine Hospital Service, has translated the report by Kitasato and his associates on the epidemic of plague at Kobe and Osaka, Japan. This report was also translated for the *Philadelphia Medical Journal* by Dr. M. Ostheimer, and published as a special article in our number for January 19th, 1901. A crusade was carried on against rats at both places, the government paying 2 1-2 cents a head for them, dead or alive. About 20,000 were paid for at Kobe and 15,000 at Osaka. These were by no means all the animals that were destroyed. Only about one-tenth of the rodents killed at Osaka were infected, and about one-fifth at Kobe. The relation of rats to the spread of the disease is not apparent, for the territory in which pest rats were found was much more extensive than that in which plague occurred in the human population. This seems to indicate that rats do not spread plague very actively among the people, but are simply themselves victims of it. They seem to take the disease before the human subjects. In Japan, it seems, the rat is looked upon as a sort of guardian angel of the household, and its destruction is, therefore, not easy.

The report does not contain much that is new. Carbuncles occurred as primary lesions, and not always secondary, as the Germans have contended. Buboës of the cervical and submaxillary glands were comparatively common, and the authors believe that these were secondary to infection through the tonsils. In fact, they attach much importance to this mode of infection, and regard the tonsils as important foci from which to make cultures. The most fatal form of the disease was the pneumonic, and it was also the most dangerously contagious. Instances are given of deaths in a few hours. One reads with some astonishment that a woman nurse, after having nursed a malignant case of pneumonic plague, when she might have been supposed to be infected, was given Haffkine's prophylactic. She promptly developed the pneumonic form of the disease and died. This practice, we had supposed, was always strongly contraindicated. Kitasato claims that the diagnosis of plague can only be made with certainty by bacteriological tests. Shiga prepared a prophylactic of his own, made somewhat after the method he used for obtaining a prophylactic against the Japanese dysentery. The technique is described in full in the report, but not much is said about the successful use of this agent. We are much impressed on reading the report with the scientific method and thoroughness of the Japanese physicians, except as to the use of Haffkine's prophylactic.

Removal of the Superior Cervical Sympathetic Ganglion for Glaucoma.—In 1898 Jonnesco, of Buda Pesth (*La Presse Medicale*, June 6, 1898), suggested and practised the removal of the superior cervical sympathetic ganglion for the relief of glaucoma, the object being, of course, to permit the third nerve to contract the pupil and to relieve the intra-ocular tension by the paralysis of the sympathetic fiber that pass through this ganglion. He operated upon 7 cases with asserted good results. The wave of eagerness to remove portions of the nervous system that has recently swept over the medical world and has had such disastrous results upon the integrity of the Gasserian ganglion, naturally aided the results described by Jonnesco to secure followers; and Dodd, in England (*Lancet*, October 19, 1900), and Coover, in America (*Phila. Med. Jour.*, March 16, 1901), have reported cases. The former obtained transient improvement, that is, contraction of the pupil, soft, normal tension and cessation of the pains; but there was prompt relapse to the original condition. The latter did not succeed even so well, tension remaining plus 1, and the vision relapsing on the 12th day. In view of these results by reliable men, it would seem that Coover's opinion is thoroughly justified, that it is an operation of

last resource, and even then offers very little hope of permanent relief. It is universally admitted, however, that it is easy and safe, and it is, therefore, perhaps, to be tried. Dodd does not approve of the bilateral operation at one sitting.

Temporary Ligation of the Common Carotid as a Preliminary to Resection of the Superior Maxilla.—The last issue of the *Philadelphia Medical Journal* contained a most interesting and scientific discussion by Professor Carl Schlatter, of Zurich, on the advantages and dangers of both temporary and permanent ligation of the common carotid artery as a preliminary procedure to the removal of the upper jaw. The question of the advisability of first ligating the external or the common carotid has long been one for discussion and disagreement among surgeons. This able paper would certainly tend to put aside many objections that have been raised against the temporary ligation of the common carotid. Although in many instances the ligation of the external carotid is sufficient to prevent hemorrhage during the operation, yet there are cases, such as one reported by Professor Schlatter, where this ligation does not prevent the hemorrhage. The cerebral complications which have so frequently followed the permanent ligation of the common carotid do not arise when a temporary elastic ligature has been properly applied to this vessel, for under such circumstances there is no formation of a clot, and consequently no danger from emboli. The blood control during the operation of removal of the superior maxilla is always a question which concerns the surgeon, and Professor Schlatter shows that the mortality from the operation is much higher and the chances of recurrence of the malignant growth much greater where no means are employed to prevent hemorrhage before beginning the excision. Another advantage which is urged for the exposure of the carotid is the important fact that in carcinoma of the upper jaw the glands about the bifurcation of the carotid are the first to become involved in the malignant process, and are always diseased before they can be felt by the hand of the surgeon. Therefore, the incision necessary for the ligation also permits of the removal of these glands. The literature of this operation has been carefully studied and the conclusions arrived at by the author must appeal to every surgeon.

The Effect of Alcohol on Immunity.—In this age of rapid scientific advancement, when old cherished beliefs are shattered by newly discovered facts, our therapeutics are also subjected to a thorough revision. It appears that just now alcohol is bearing the brunt of a searching investigation. So long

as the question of the use or abuse of alcohol remained a purely sociological problem, the physician could have but little to do with it from a scientific standpoint. Even if in sympathy with the anti-liquor movement, he still used alcohol as a medicine, firmly believing that it was the remedy par excellence in acute infectious diseases. This well-established belief, expressed *ex cathedra* by our textbook writers and eminent therapists, has received a crushing blow at the hands of Doyen, Abbot, Verlaguss, Ranelletti, and a number of other scientists, who have investigated the effects of alcohol experimentally. The unanimous verdict is far from being in favor of this "health-restorer." Recently, Dr. S. I. Goldberg instituted the following experiments in the Bacteriological Laboratory of Prof. Tshistovitch (Russia). He divided a number of pigeons into three groups. Those of the first group received an injection of a non-fatal dose of a culture of the plague bacillus, and with it, or during several days subsequently, medium and large doses of alcohol introduced by means of a sound. The pigeons of the second group received small doses of alcohol for a considerable time prior to inoculation. Finally, those of the third group received a fatal dose of the culture, and for several days afterwards small doses of alcohol twice daily. The conclusions reached were as follows: (1) pigeons, which are but slightly susceptible to the plague, had their susceptibility greatly increased by small doses (2-3c. c. of 40% alcohol), which were sufficient to produce intoxication. (2) Chronic alcoholism lowered the natural resistance of the pigeons to the plague. (3) Small repeated doses of alcohol did not save the birds after a fatal dose of the plague-culture.

These and other experiments of a similar nature, recorded in recent medical literature, seem to indicate that alcohol, even in small doses, exerts a deleterious effect on the cells proper, and while possessing high caloric value, as proven by the experiments of Atwater, it is, nevertheless, a cell-poison. It, therefore, seems that its continued use in acute infectious diseases should tend to produce precisely the effects against which it is directed. The results of mere laboratory experiments on the lower animals must, however, be received with some caution. Experimenters frequently arrive at opposite conclusions, especially on the subject of alcohol, and clinical experience is not lightly to be set aside at the behest of every experimenter in the laboratories.

Specific Biological Reactions.—The discovery that the injection of blood of one species into animals of another species produces substances which

are destructive to the blood of the species from which the injected blood was derived, has opened the way to investigations which are of almost unlimited extent and variety. A number of these reports have recently been abstracted in this journal, most of them referring especially to the reactions in blood. Among the most interesting was that of Uhlenhuth, who stated that the result of the injection of blood from one species was to produce some substance, which, when added to a solution of blood from the original species, even when that blood had been dried for a long time, caused a definitely recognizable reaction, even in extremely dilute solutions. He claims that the reaction is absolutely specific, and can be used for distinguishing human blood stains for medico-legal purposes. His results have been confirmed, though the absolute specificity of the reaction has been denied. There have also been numerous other reports showing most interesting results. The most suggestive of these was the demonstration that the injection of ciliated epithelium produces a substance which dissolves the same variety of epithelium, but has no action upon other cells. This must have shown at once to many readers the possibility of producing in this way an actual specific cancer serum, though, unhappily, this possibility seems as yet a very distant one, and one hedged about by many and great difficulties, in spite of the work recently referred to editorially. In addition to these reports, Delezenne has recently stated that he has produced anti-hepatic and anti-nervous serums, these serums having destructive effects upon the liver and nervous system respectively, and being produced by injecting emulsions of these organs into creatures of a different species. The most striking fact recorded by Delezenne was his observation that if these toxic serums were administered in frequent but very small doses, they had directly the contrary effect, the animal being soon made almost absolutely resistant to the effect of large doses. This approaches very closely to the production of serums specifically anti-toxic to those substances which act directly upon various organs, and suggests most astonishing possibilities. The most recent use of this method is described by Mertens (*Deutsch Med. Woch.*, March 14, 1901), who states that he has shown in a manner that is almost absolutely conclusive that the albumin in the urine in nephritis is directly derived from the blood, thus almost definitely settling a question which has given rise to much discussion. His statement is based upon the fact that he injected rabbits with human blood serum, and afterwards found that the rabbits' serum caused a marked reaction with human urine containing albumin, but did not react with

human urine free from albumin or with the urine of normal rabbits or of rabbits which showed marked albuminuria. Further, the injection into rabbits of human urine containing albumin was followed by the production in the rabbit's blood serum of a substance which gave exactly the same reaction as that produced by the injection of human blood serum. This is almost absolute proof that the albumin in the urine and the albumin in the blood serum are exactly the same biologically, and probably chemically. A most interesting observation was the fact that the serum of a new born rabbit, whose mother had been treated with albuminous human urine, reacted in the same way as the serum of the mother. Mertens considers that his results demonstrate that the serum of transudates will react in the same way as the blood serum, and that transudates may be used for injection instead of blood serum. He also believes that it will be possible to use albuminous urine instead of blood serum; since albuminous urine is so much more readily obtained than human blood serum, this will greatly widen the opportunities for this method of research. The constantly increasing number of reports similar to this one must convince those who are abreast of the literature that the possibilities in this line are so great that most important discoveries may be expected within a very brief period. We seem to be on the verge of a new era, both in the experimental study of abstract biological questions and in therapeutic advances, which are directly connected with these biological studies, and which will be of most grateful portent to those sufferers who have heretofore been beyond anything better than palliation.

Three Medical Worthies.—In the *Popular Science Monthly* for April, Professor William A. Locy pays a graceful tribute to a triumvirate of medical investigators, whose names abide in medical tradition, but whose work is too likely to be forgotten. As Professor Locy well reminds us, we are too apt to think that all the really good work, especially in biology, has been done in very recent times, with modern methods and modern insight. A glance at the work of Malpighi, Swammerdam, and Leeuwenhoek, is a good corrective for some of this modern self-laudation. These three men, not personally associated, were contemporaries and represented that revival of science which characterized the 17th Century. The watch-word of that century was *observation*. Knowledge was to be gained by direct appeal to Nature herself, and the books and formula which had dominated the dark ages were discarded. In this one vital respect this was an age of pure scientific method, and quite equalled our own in the zeal and consistency with which men sought to wrest

from Nature herself the secrets of morphology and even of life. The pioneers had been Vesalius, Galileo, Harvey and Descartes, and our three medical worthies were of only one generation later.

Malpighi was an Italian, born near Bologna in 1628. In his discoveries, and in the position he occupies in the history of natural science, he deserves the title of an original and profound observer. He studied not so much the gross, but the finer anatomy of animals, and pursued his studies also in the vegetable kingdom. He was one of the founders of modern histology, and did extraordinarily fine work, considering his instruments. His drawings of the anatomy of the silk worm are models of accuracy. Insect anatomy was an unknown field, and here Malpighi demonstrated for the first time the dorsal vessel, the tracheal system, the stomach and the reproductive organs. His work in embryology was remarkable, and his drawings look as though they came out of some modern laboratory. He also observed the blood corpuscles, and his name is identified with the anatomy of the kidney and spleen.

Swammerdam was a native of Holland, and his portrait by Rembrandt is preserved. He was an indefatigable worker and an expert draughtsman. He also, like Malpighi, did some exquisitely fine work in entomology, and helped to establish biology and morphology on an enduring basis. His drawings were even better than Malpighi's, and were veritable works of art. No one can look at the reproductions of some of them and not be impressed with the excellence and variety of such a gift in a scientist. Swammerdam opposed the theory of spontaneous generation, which in his day was actively debated. He was a believer, however, in the "preformation" theory, which was that an animal was fully formed in the ovum—an idea which has its nearest modern analogue in the theory of pangenesis.

Leeuwenhoek was an ardent microscopist, and owned no less than 247 complete microscopes—though what he wanted with so many does not appear. In addition, he had 172 lenses. Many were mounted in silver and a few in gold—such was the vanity of science in those days. His microscopes, however, were made without tubes; the lenses were merely held in place on pieces of metal, with screws to adjust the object and secure focus. Leeuwenhoek's great merit was to have demonstrated the capillary circulation. He sought it in the comb of a cock, the ear of a white rabbit, and the wing of a bat. But finally his search was rewarded by finding what he sought in the tail of a tad-pole. His description is replete with the enthusiasm of the simple-minded naturalist. Leeuwenhoek also made observations on the blood corpuscles, although he

had been anticipated by Malpighi; but these two were among the first hematologists.

Even a brief study of the lives and work of these famous scientists is of great profit, for it gives to us, of the present day, a more adequate conception of the universality of science and of the great attainments of some of the old and well-nigh forgotten worthies of medicine.

The Relations of the Purely Scientific Studies to the Physician's Work.—In a paper published in the *Boston Medical and Surgical Journal*, April 4, 1901, H. D. Arnold makes the following statement: "The average practitioner is apt to rest satisfied, if, by discovering a murmur, he is able to point out the site of the lesion and can give an anatomical name to the disease. Fortunately, for both patient and physician, the heart generally has wonderful recuperative powers, if given half a chance. Rest, with or without medication—and sometimes in spite of bad medication—furnishes the opportunity, and we take credit to ourselves for an improvement which was due to nature, and neither to our thorough understanding of the condition, nor to an intelligent application of remedies." This statement in relation to heart disease may, with certain modifications, be applied to diseases of other organs, and should, we think, be forcibly and frequently brought to the attention of the medical student. Many a student is prone to think, as he sits on the benches during his first and second years of medical study, that the details of chemistry, anatomy, physiology, and pathology, which he is expected to master, have really little to do with the work of his profession, and in this opinion he is often confirmed by the attitude of his acquaintances, who have completed the prescribed four years of study and have begun practice. So when the student reaches his third year and begins the study of the practice of medicine, he is prone to give scant attention to the pathology and the differential diagnosis of the diseases as presented by his instructors; but so soon as a prescription is put on the blackboard, he copies it with an energy that might better be expended in mastering the natural history of the disease in question. The savages beat upon drums, hoping by the din to scare away the evil spirit of the disease and thus renew the vitality and usefulness of the afflicted one. The civilized races go to a physician, expecting to receive a drug or a series of drugs that will kill the same evil spirit of disease and render them immune, while they hold fast to their habits of unhygiene and of exposure. Drugs have not this magic charm, and those practitioners who have misapplied their energies during their college days, as well as the students who are now learning of the mysteries and the frailties of the human body,

should bear constantly in mind that the normal and pathological anatomy and physiology which they are expected to understand will go farther toward fitting them to teach their patients the true secret of health than the mere knowledge that such and such a prescription is good for this or that disease. So, too, the mere ability to recognize and locate a cardiac murmur or a bronchial rale, to find tube casts, or to discover albumin or sugar in the urine, will avail little unless the fundamental principles of the cause, course and lesions of the disease producing these symptoms be thoroughly understood.

The Census of India.—According to the *British Medical Journal*, the census of India was taken very quickly and accurately, for the preliminary figures were published fourteen days after the date for counting the population. There are some details in this census that are of interest to medical readers. The total population of India is hardly as great as is generally supposed. It is shown by this census to be 294,266,000, a gain of 6,949,000, or 2.42 per cent. since 1891. The increase revealed by the census of 1891 was 11.2 per cent.; therefore, there appears to have been some check on the growth of population in the great Hindoo peninsula for the past ten years. What this check consists of is, perhaps, not difficult to determine. India has been swept with famine and pestilence. Even allowing for greater accuracy in counting the population (a factor which always rather tends to lessen than to increase the figures), the fact remains that this census is a mournful object lesson for mankind in general.

The territory directly under British rule shows an increase of 4.44 per cent. The facts all told are capable of but one interpretation. The native States have not, as a rule, met the emergencies caused by the plague, cholera and the famine, with the same intelligence as has been shown by the British Government in the territory directly under its control. The figures, however, vary for the several native States, and in some instances the population has increased; but the deduction just stated is probably in the main correct. Natural causes also explain the figures; thus those parts of India which are well watered—whether British or native—and which, therefore, escaped the famine of 1897 and 1900, show an advance. The traces of the famine and its twin progeny (pestilence and impaired fecundity), are very evident in these returns. Even in famine-stricken areas the loss of life was less under British rule than under native government. This is a satisfactory proof of the efficiency of good government. Much remains to be worked out by a study of these figures, and this will be done by Mr. H. H. Risley, the Census Commissioner, whose

studies will doubtless bring out in full the relation of famine and pestilence to the arrest of population in this teeming region of the world.

Reviews.

Infant Feeding in Health and Disease. By Louis Fischer, M. D. Octavo 359. F. A. Davis Company

The volume opens with brief remarks on the anatomy of the infantile stomach. There is then a satisfactory short account of the chemistry of the digestive secretions. We find an unnecessarily full description of various forms of bacteria actions present in the gastrointestinal tract, marked details which only a specialist in bacteriology needs or would understand. The chemical and physical properties of bovine and human milk are treated of extensively, as is the whole subject of artificial feeding. There are given some useful analyses of various commercial foods, and a serviceable chapter on infant stools. Finally we find a dietary containing many good formulae at times of value. We have read Dr. Fischer's little book with much interest and considerable care. We are sorry that we found in it an unusually slovenly and often ungrammatical use of the English language. One wonders what had happened to the publisher's reader. Note, for instance the following remarkable sentences: "The investigation of Leo and von Puteren show that the gastric contents are propelled within from one and a half to two hours. With food that is more difficult to digest the stomach is emptied much slower and less complete." "Another nipple I have used, but it is much harder to clean, and, unless all precautions for sterilization are noted, this nipple should not be used; yet, in the hands of the intelligent, or where we have a trained nurse, it can be safely recommended. It is called, etc." A much more serious and vital fault is the author's evident searching for evidence in support of certain pet views, with his ignoring of what could, and should, be said upon the other side. That which the experience of many physicians has proven useful is considered utterly without sufficient reason given, and that which is unusual and not generally accepted is in terse manner praised, and its truth sometimes simply assumed. This makes the book an unsafe guide. Yet the little volume in this respect shows a conscientious study of recent and older scientific work done in the domain of infant feeding, and contains a large number of references and quotations, which will be serviceable to those desiring to make milk a study for themselves. To those we can heartily recommend it. [C. G.]

A Laboratory Guide in Elementary Bacteriology. By William Dodge Frost, Instructor in Bacteriology, University of Michigan. Illustrated. 1900. Published by the Author, Madison, Wis. 200 pages, 8x10 $\frac{3}{4}$ inches.

This laboratory guide opens with a list of texts and reference books, list of apparatus and a few concise laboratory rules. Following this the work is divided into two parts, Part I dealing with general bacteriology and Part II with medical bacteriology, the two parts embracing 10 chapters numbered continuously through both.

Directions for the preparation of containers, media, stains and directions for drawing and special stains are given in Chapter I. Chapter II deals with the physiology of the bacteria, with methods for determining reaction, influence of physical agents, color production, etc. Chapter III, taxonomy and subsequent chapters are largely given to the study of special organisms.

In the first 50 pages and occasionally elsewhere, alternate pages are left blank for notes. The tables given for the study of bacteria strike the reviewer as being of very great value as indicating to the student the steps to be worked out and the data to be recorded.

Chapter VIII dealing with animal inoculation and staining of bacteria in tissue could be elaborated to advantage. There is less than one page to the detection of pathogenic bacteria in water and milk supplies (Chapter X). It might have lessened the confusion in the student's mind had

synonyms for all organisms been given as has been done in the case of pneumococcus.

The paper is good and the typography and tabulation are fully acceptable. The copy sent out for review has evidently been very poorly seasoned and cannot be kept flat. As the book is intended for the laboratory the reviewer would suggest to the author, who is also the publisher, that it be bound in one of the forms of rubber cloth now used for manuals of dissection.

The book will undoubtedly be an acceptable guide for use of the student and even for the investigator as a convenient blank for recording results. [W. M. L. C.]

A Text-Book of the Medical Treatment of Diseases and Symptoms, By Nestor Tirard, M. D., Lond., F.R.C.P. Professor of the Principles and Practice of Medicine, King's College, London, etc. Adopted to the United States Pharmacopoeia by E. Quin Thornton, M. D., Demonstrator of Therapeutics, Pharmacy and Materia Medica, Jefferson Medical College, Philadelphia. 8vo, pp. 630. Philadelphia and New York: Lea Brothers Co.

This book is intended to bridge the gap between the instruction in therapeutics as given in text-books on the practice of medicine, and such treatment of the patient as is needed at the bedside. The author very properly says that a student may know many diseases and symptoms for which a particular drug such as digitalis or belladonna, may be employed, and yet scarcely be prepared with the various drugs serviceable in the course of treatment of any individual disease or treatment of almost all the local and constitutional diseases and of permanent symptoms such as vomiting, gastralgia, constipation and night sweats. The advice given is helpful, and even those having considerable experience in the treatment of diseases will find valuable suggestions in many places. [H. B. A.]

The Morphology of the Blood in Diphtheria, Scarlet Fever and Scarlatinoform Erythema. Pitkianen (*Peterburgskaia Dissertatsia*, 1900), found that in mild cases of diphtheria a moderate hyperleukocytosis is present in the first stages of the disease, gradually disappearing as improvement sets in. Polymorphonuclear leukocytes are in some cases increased, while in others remain normal; as improvement progresses, their number gradually diminishes. Eosinophiles are absent in the first stages of the disease, but make their appearance as the disease advances toward a favorable issue. Similar conditions are observed in cases of diphtheria of moderate severity. In severe cases of hyperleukocytosis is marked from the beginning and persists during the entire progress of the disease. The polymorphonuclear leukocytes are increased at first, diminish gradually and are again increased if the disease terminates fatally. Eosinophiles are invariably absent in fatal cases. The presence of the eosinophiles or their increase in diphtheria is a favorable prognostic sign; their absence for three or four days, on the other hand, points to a fatal determination. The morphology of the blood in non-diphtheritic sore throat is similar to that of mild cases of diphtheria. A marked increase of the latter is found in scarlatinoform erythema. [A. R.]

Tannalbin, Tannigen and Tannoform in Intestinal Diseases of Children. Preis (*Trudi Obshestva Russkich Vratchei v Moskvie*, 1900), tried the above remedies in 148 cases of various intestinal disturbances of children, the doses employed being 0.03-0.06 grms. for a child one month old, 0.1 for one 2 months old, and 0.2 for a 3-months-old child. The results obtained were as follows: Tannalbin proved successful in intestinal indigestion, acute and chronic catarrh of the small intestines and in tubercular diarrheas. Tannigen failed to produce any beneficial effect in every case it was used. Tannoform was successful in only a few cases, namely, in acute and chronic intestinal catarrh, cholera infantum and tubercular diarrheas, but even in these cases the effects were inconstant, and only children not younger than 2-3 months were benefited. [A. R.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Wills' Hospital Ophthalmic Society.—Meeting held in Philadelphia, 25th March, 1901. Dr. P. N. K. Schwenk in the chair. **Primary Sarcoma of the Iris.**—Dr. Conrad Berens presented a most interesting case illustrating the secondary stage of primary sarcoma of the iris. The patient, a young man, who was free from any symptoms and obtainable history of syphilis or tuberculosis, first noticed the affection some three years previously. Imbedded in a partially degenerate and comparatively uninfamed iristissue were five irregular tumor-masses, over and through which some fine vessel ramification could be plainly seen. The plane of the iris was pushed forward. The pupillary area which was slightly distorted, contained some meshes of glistening lymph. The crystalline lens occupied its normal position. No view of the fundus could be obtained. Intraocular tension was increased to plus two. No view of the fundus could be obtained. Intraocular tension was increased to plus two. There was not any ciliary tenderness. Based upon these findings and the fact that the therapeutic tests for syphilis and tuberculosis had been unsuccessfully applied, Dr. Berens felt certain of the diagnosis, and believed that it would be proven after enucleation. Dr. Frank Fisher tended to the opinion that there might be an iridocyclitic element in the case. Dr. William W. McClure agreed in the diagnosis, giving a number of differential points between the one almost certain and the other possible processes. Dr. Charles A. Oliver, while fully agreeing in the etiology of the condition was disposed to place the main bulk of the growth in the ciliary body. **Embolicism of the Central Retinal Artery.**—Dr. Frank Fisher exhibited a series of water-color sketches of several stages of a case of embolicism of the central artery (full details of the case to be published in full later). The patient, a young subject with a mitral murmur, gave the usual history of sudden blindness. Besides the characteristic eyeground of the affection, all of the main retinal blood currents, both arterial and venous, were found to be interruptedly flowing in their proper directions; the curious fact being that the venous currents were travelling with twice the rapidity of the arterial. Dr. McClure stated that he had had the opportunity to see two cases in their very earliest stages. One of the early changes he had found, consists in a lead-tinted area bounded upon its superior and inferior borders by two fine vascular twigs that are not ordinarily observable, giving the area of infiltration a caudate form. The second of his cases which but partially closed the arteries, showed broken blood currents in the two principal veins running in the direction of that which is pursued by the ordinary contained blood. Dr. Schwenk had seen six clinical cases of central retinal artery embolicism, one of which occurring in Dr. Harlan's service at the Hospital and which showed the vascular beadings, he had made careful drawings of, these being published in the Transactions of the American Ophthalmological Society. His experience had been that vision seldom if ever returns in the pronounced types of the disorder. Dr. Charles A. Oliver was greatly interested in the double rapidity of the venous current seen in Dr. Fisher's case, and spoke of the difference between trophic and functional disturbance found in these cases, drawing attention to the two forms of vascular circulation in the human retina. He made mention of the possibilities of endarteritis, vessel-spasm and thrombus in such cases, and did not deem a differential clinical diagnosis in such cases as entirely certain in every instance as the several conditions might be coexistent. Dr. Walter L. Pyle called attention to several cases in ophthalmic literature, in which although there was complete embolicism of the central artery, a small sector in the field of vision was preserved; ophthalmoscopic examination showing a cilio-retinal artery, supplying the corresponding retinal area. Dr. Fisher did not believe that there was any collateral retinal circulation. He considered the most remarkable feature in his case to be the visibility of both the arterial and the venous circulations in the retina at the same time. He deemed prognosis as to vision doubtful when an embolicism is situated within the retina as it is not likely to undergo absorption in such a position. **Successful Extraction of Manganese Steel from the Cry-**

talline Lens.—Dr. Schwenk showed a forty-five year old man from whom he had successfully removed a piece of manganese steel from the left lens. The points of interest in his case consisted in the facts that the form of steel which was imbedded in the lens substance was but feebly attracted by the magnet and that much of the lens matter which had appeared transparent at the time of the removal of the foreign body afterwards became opaque and greatly swollen. Dr. McClure gave the details of a case of steel in the lens in which, before making the corneal section with a von Graefe knife, he created a path or track through the lens fibres with a Hay's needle for the escape of the foreign body. After this was done, it was but necessary to bring a magnet tip to within two inches of the external wound, the foreign body fairly leaping out of the eye though its open pathway. The lens mass was then expressed without any trouble. Recovery was uneventful, a corrected vision of two-thirds of normal being later obtained. Dr. Oliver stated that not sufficient attention had been paid to the relative traction qualities of the different forms of steel, all being classed alike. He believed that extremely hard and brittle manganese or nickel steel are so dense and contain so much nonmagnetic material that the electric current cannot permeate the mass sufficiently to attract enough of the ferric elements to produce expulsion of the foreign body unless the magnetic force be very greatly in excess of that which is obtained by the ordinary forms of clinical magnet. He also called attention to the fact that on account of the very great brittleness of manganese steel, workmen should be taught to be extremely careful in the handling of such material as it is particularly liable to fracture. In all his cases where permissible, he removed as much of the clear lens material as possible, this being readily accomplished by means of a grooved spud. Dr. Berens made it a rule to evacuate all of the clear lens matters that he could with safety to the organ. **Removal of Congenital Cataract.**—Dr. Oliver exhibited a nine year old Hungarian boy from whom he had successfully removed two congenitally opaque lenses by free dissection, obtaining a corrected vision of normal in each eye. The case was of interest as showing the good effects of diametrically opposed forms of treatment in the two eyes, necessitated by an attack of secondary glaucoma from stoppage of lymph flow caused by a blocking of the pupillary area. He did not consider such a complication of any great moment in the young otherwise healthy eye as it rapidly subsided under appropriate treatment without any damage to the organ. Dr. Schwenk presented a case of congenital cataract in a white male of thirty years of age, the interesting point being that three brothers were similarly affected, while three sisters had normal eyes. Ten days previous, a free dissection of the right lens was done by the Senior Resident Surgeon of the Hospital. The lens rapidly swelled and several opaque pieces of matter fell into the anterior chamber. One week later, although intraocular tension was normal and the eye was quiet, much of the remaining lens material was extruded by means of a grooved spud. At present the eye is practically well. **The Immediate Results of Mules' Operation.**—Dr. Oliver showed the immediate results of a Mules' operation in a case of panophthalmitis. The patient was a twenty-three year old sailor who had lost his eye about a year previously from gonorrheal infection. As a large area of the sclerotic coat at the upper outer corneal limbus was softened and infiltrated, he took advantage of excising this part while converting the circular corneal area into a lozenge of sufficient size to admit the placing of the glass ball into the scleral cavity. In less than five days' time without any reaction, the conjunctival sac was clean and the eyeball was freely mobile. In accordance with a suggestion from the Senior House Surgeon of the Hospital he had most successfully employed pressure bandages instead of the usual feed compresses. He expected, as is his rule, to discharge the case from the wards of the Hospital as cured in a few days' time. He will order a properly adapted artificial eye for the patient as soon as the socket becomes fixed in size. He had learned from experience that throughout the entire procedure it is always best to avoid touching the borders of tissue intended for coaptation by any fixing instruments, and always to remove the ocular contents with a number of moistened cotton swabs twisted upon the end of clean applicators. He has broadened the

field of the usefulness of the procedure to cases in which he had previously had no expectation of good results, employing the plan with immediate cessation of all inflammatory signs in cases of panophthalmitis and even localized tenonitis in which even isolated areas of softening in the anterior portion of the sclera had become evident.

A Medical Club Chartered.—Judge Ralston approved the charter of the Ptolemy Society, a corporation formed for social intercourse and to disseminate medical science. The officers are: President, Stilman Henry Conner; vice-president, Bert Edward Goodman; secretary, Atlee David Mitchell; treasurer, Frank Cornelius Leytze, and Board of Governors, Drs. Hiram R. Loux, Hobart A. Hare, Justus Sinexon, Dudley D. Smith and Edwin Russell Kennedy.

Epipoplexy.—Dr. James T. Jelks, of Hot Springs, Arkansas, informs us by letter that his recent interesting paper on this subject which appeared in the *Medical Record* (March 23rd), was read before the Texas Medical Society, and consequently before the appearance of Dr. John B. Roberts' paper on the same subject in the *Philadelphia Medical Journal* for January 26th. This accounts, of course, for Dr. Jelks' not having made reference to Dr. Roberts' paper.

Appointment.—Governor Stone has appointed Professor L. Webster Fox a member of the Board of Managers of the Orthopaedic Hospital and Infirmary for Nervous Diseases, of Philadelphia.

Jewish Maternity Home.—The number of patients received at the Jewish Maternity Home in March was 10; cared for during the month, 14; applications, 15; births, 8; operations, 9; discharged, 9; remaining, 5. In the clinic 25 new patients, 21 old patients and 12 eye patients were treated. In the Nursery for Motherless Infants there were 6 admissions, added to 7 remaining from February made 13 cared for; discharged, 8; in the nursery March 31, 5.

Dr. Henry S. Clemens.—Dr. Henry S. Clemens, of Allentown, Pa., died April 8th, aged 63 years. He was graduated from the University of Pennsylvania in 1861, and for the last thirty years practiced his profession in Allentown.

Berks County Medical Society.—At the April meeting of this society Dr. Jno. Bertollette presented the history of a case of elephantiasis that came under his care. The patient being a woman of 51 years of age, no children, both parents living to old age. The foot measured 15 inches in diameter, the leg 12 inches. Dr. Bertollette states that the itching of the parts was so intense at times as to necessitate the use of brushes to allay the itching. Dr. J. C. DaCosta, of Philadelphia, spoke of the pathological changes found in the case. Dr. Bertollette exhibited the filaria under the microscope. Dr. Weidman and Dr. Frankhauser spoke of a case that was in the Reading Hospital some ten years ago, Dr. Weidman amputating the leg at the lower third of the thigh, the patient is still living, with no recurrence of the disease. The specimen is in the Pathological Museum of the Reading Hospital.

Vital Statistics of Philadelphia for the week ending April 13, 1901:

Total morality 469

Cases. Deaths.

A MARTYR TO SCIENCE.

Dr. Ralph Erskine Johnston.—Dr. Johnston was born January 1st, 1867, and was killed by an insane patient in the Danville Asylum on April 3rd, 1901. His name shows his Scotch ancestry, he being descended from Sir Archibald Johnston, of Scotland, who was martyred for adhering to the "League and Covenant." His father, both grandfathers and remoter ancestors were all Presbyterian elders, and he himself was an adherent of that church. He was bright and precocious, besides having a practical turn of mind, which enabled him to take up many lines of thought or action. Even as a boy, he showed a capacity and a delight for "doing things," as making toys, building machinery, painting, drawing or taking up a mechanical pursuit like photography, or a line of investigation, like his family genealogy. He attended the district school at the home of his father, near New Wilmington, Pa. There he entered Westminster College, New Wilmington, graduating in 1889, at 22. He then spent some time as an attendant at the Dixmont Hospital for the Insane, where he had been previously employed. Here he acquired a taste for work among the insane, which never left him, and which led ultimately to his death. From Dixmont he went to Cleveland, spending a year at the Medical College. He graduated from the College of Physicians and Surgeons at Baltimore in 1894. He had a short term of service at the city hospital, Cumberland, Md., which he resigned to take the

DR. RALPH E. JOHNSTON.

position of Assistant Physician at the State Hospital for the Insane, Danville, Pa., September 1st, 1894. To a considerable extent Dr. Johnson was "self-made," earning the money for his education as he went along. He was practical and excelled in practical pursuits; was a good amateur photographer, and prepared slides for his stereopticon lectures at the hospital; was fond of electrical engineering; was an enthusiastic botanist; and was musically inclined. Though his life and character were many sided, he was always at his post of duty, and died there. A careless physician would have left the trifling ailment of the patient pass, but Dr. Johnston felt it to be his duty to attend him, and was murdered by the man he was

attempting to benefit. Though his life was short, he has not lived and died in vain. His death may save the lives of others by making them more careful in dealing with the insane. His life may be an inspiration to all, for he was fearless, yet kind; serious in business, yet gracious in social intercourse. In all the private relations of life he was tender and true, as a son, a brother and husband. His relatives cherish his memory in the most grateful remembrance, while the hospital and acquaintances of Danville feel his death as a personal bereavement and most deplorable murder. Dr. Johnston was married to Miss Augusta Sweisfort, daughter of Col. Jonathan Sweisfort, of Danville, Pa., January 8th, 1901. The insane man responsible for Dr. Johnston's death, an Italian shoemaker, has been a resident of the institution for three years, and was a case of mania with delusions of persecution, quarrelsome, denunciatory and threatening, very excitable and quickly angered. Because of these characteristics he had been frequently searched, the last instance being the day previous to the assault, all clothing being removed. On the day in question the patient complained of illness and was put to bed, he, however, requesting that the physician should not disturb him. During the usual evening round Dr. Johnston entered his room accompanied by a nurse, despite the protest of the patient, sat upon the edge of the bed and endeavored to take his pulse. To overcome the patient's hesitance the nurse was directed to hold his hand, but before this could be secured he had dealt the doctor a blow with some sharp-pointed instrument on the left lower jaw near its angle. In attempting to subdue the patient Dr. Johnston received three additional wounds in quick succession, one in the right shoulder, one in the left hypochondriac region, both superficial, and a fatal stab wound about one and one-half inches below the clavicular notch, penetrating the sternum, pericardium and arch of the aorta about one and one-half inches from its origin, the puncture being about one-fourth inch long. The hemorrhage into the pericardium caused death in about twenty minutes. The weapon with which the deed was done seems to have been the small blade of a pocket knife found secreted in the crack of a ward settee outside the patient's room. In justification of the act the patient stated they were trying to kill him.

NEW YORK.

New York Academy of Medicine—Section on Orthopedic Surgery.—Meeting of March 15, 1901. George G. Elliott, M. D., Chairman. Dr. Homer Gibney presented a boy aet. 11 years, who had infantile spinal paralysis. There was equino-varus of the left foot with slight cavus. According to previous history, astraglectomy had been performed 5 years previously without beneficial results. November last Dr. Gibney exposed the tarsal bones, curetted the cartilages, sutured the wound and applied a plaster of Paris bandage. The result was that the foot was shown at a right angle with slight motion. **Acute Hip Disease.**—A second patient, a girl 6 years of age was shown by Dr. Gibney. She was suffering from acute hip disease when first seen in October, 1899. A brace was applied and the child put to bed. Her hip became worse; the hip was stretched and a plaster of Paris spica was applied. An abscess developed and was opened January, 1900. Improvement followed the incision but owing to a profuse discharge, fever and loss of flesh the hip was excised April, 1900. The child improved rapidly after the operation; a small sinus remained. **Paraplegia Complicating Spinal Caries.**—Dr. Gibney presented a third patient, a girl 9 years of age. She was admitted to hospital December, 1900, with the history that her disease followed an attack of diphtheria five years previously. A plaster of Paris jacket was worn for six weeks at onset of disease and then for eighteen months she wore a Taylor brace with head attachment. In 1897 she had an attack of paraplegia which lasted six months. One year ago she had a second attack which persisted at time of admission into the hospital. There was at that time paraplegia, incontinence of urine, increased reflexes with marked ankle clonus. December last the child was put to bed wearing a plaster of Paris jacket with head extension. The jacket was re-applied January, 1901, with head extension and plaster straps over the shoulders. A third jacket was applied February 21. Improvement was gradual and child was shown with fairly good voluntary use of legs. **Coxa Vara.**—Dr. W. R. Townsend presented a

boy 15 years old who came to the hospital for R. & C. one month ago, with the history that without any apparent cause one year previous he began to have difficulty in walking and was easily fatigued. The difficulty in locomotion had steadily increased. The limbs were equal in length and the X-ray revealed a very marked case of coxa vara. There was limitation of motion and the great trochanters were one inch above Velaton's line. Limitation of motion, especially in flexion and extension was very great. There was not over 15 degrees of motion on the right side and none on the left. Standing the knees could not be separated more than three inches. The patient sat with difficulty. A radiograph was shown. He asked if any member of the Section had seen a case of coxa vara with so much limitation of motion. **Spondylose Rhizomelique.**—Dr. Townsend presented a man 35 years old who five years ago began to have stiffness of the back and difficulty in walking. He had had two attacks of muscular rheumatism. He had had no pain excepting in the upper part of the back and when sitting. These symptoms increased until the present time; he was obliged to use crutches. The thighs were flexed on the pelvis about 20 degrees; extension and flexion were much restricted. He regarded the lesion of the hip joints and the spinal stiffness as typical of spondylose rhizomelique. He suggested a plaster of Paris jacket as of some service. Dr. Townsend showed two radiographs, one showing union of a fracture of the neck of the femur after use of a long traction hip splint (patient shown before Section January 11, 1901); the other radiograph was of a case of double dislocation of the hip joint which had been treated by the bloodless reduction eight weeks before. The picture was taken through the plaster of Paris splint.

Congenital Club Foot.—Dr. Judson presented a boy 5 years old first seen when there was marked and resistant typical double deformity which had been reduced by the painless continuous leverage of a simple brace applied with adhesive plaster and often removed for manipulation of the feet; later a walking brace had been used; all the apparatus used was of a common kind with a single invisible upright. The braces were made of tractable metal allowing change from the deformity to the normal and later to overcorrection. The feet followed these changes through force of adhesive plaster and later by body weight. At the age of fifteen months the deformity had disappeared. Treatment was resumed after seven months interval, the outer border of the feet having become slightly callous; walking braces were applied and worn for 22 months, finally laid aside January 15, 1900. On presentation the child walked and ran with normal ability and without defect in his gait. The only remaining defects were slightly shortened Achilles tendons but this was slight as he could even walk on his heels.

In this affection the following were to be considered as favorable elements.

- 1st. The certainty of rapid growth.
- 2nd. The plastic or formative condition of the parts.
- 3rd. The absence of body weight for 18 months.
- 4th. The certain affect of continuous leverage.
- 5th. The weight of the body applied on the right side of the plane between varus and valgus in virute of which the child could stamp his foot straight.
- 6th. The absence of necessity for haste.
- 7th. Use of tractable metal. An unfavorable point was the postponement of treatment till the child was two years old.

Funnel Chest.—Dr. Judson presented a man 71 years old having a deformity which although rare, has been described by a number of observers. It was a curious malformation, entailing no great disability, of uncertain origin and calling for no treatment. From an angular projection at the junction of the manubrium and the gladiolus there was a continuous depression till the deepest place was reached at the lower end of the xiphoid appendix. The cartilages of the lower ribs were prominent as usual on each side and the front of the chest, although somewhat flat, was normal except for this funnel like depression which began on each side at the nipple line and was cup-shaped at the bottom with a depth of $1\frac{1}{2}$ in., unchanged by expiration (31 in.) or inspiration (34 in.). The man said he had always been so and had never known of another person similarly affected in his family. He had eighteen brothers and sisters. He had been fond of athletic sports in

his youth, was a shoe-maker by occupation and had enlisted in the military service in 1862. There was no history or sign of rickets or spinal disease. He had been free from notable diseases of the chest or otherwise, although years ago he had been told that he had serious chronic disease. Dr. H. S. Stokes said it was difficult and frequently impossible to make a correct physical diagnosis when chest deformity existed. He cited a case of Pott's disease where the patient had been told four years ago that he had pulmonary tuberculosis and a bad prognosis had been made. He had frequently examined the sputum of the patient with negative results; all segs of lung involvement disappeared. He cited two cases of lateral spinal curvature which had lately come under his notice, where errors of diagnosis had been made. In one the diagnosis of tubercular consolidation was made. In one the diagnosis of tubercular consolidation was made which turned out to have been only a slight bronchitis. Dr. Myers presented a case of polio-myelitis in a boy 13 years old; the disease dated from early infancy; the case was exhibited to show the muscular changes—the right quadriceps was completely paralyzed and the right ligament patella was one inch long; the left quadriceps was fairly strong and the lig. patella $2\frac{1}{4}$ inches long. Osteotomy had been performed on the right side for a recurring genu valgum which had been caused by the greater power of the ext. hamstring muscle. The muscle was split and one-half transplanted and given to the internal hamstring and the knock knee did not recur. He called attention to the marked rotary lateral curvature of the whole dorsal spine with convexity to the left the stronger side, while concavity was toward the side of paralysis of the lower extremity and erector spinal muscles. In club foot due to polio-myelitis, the shortening always occurred in the stronger or least paralyzed muscles; by analogy the erector spinae muscles on this boy's left side, those least paralyzed should be contracted and they were. This drew the entire thorax strongly to the left and downwards. To maintain his equilibrium the boy had thrown his head and shoulders to the right by voluntary effort inducing the form of curvature present. **Congenital Dislocation of Hip with Fracture of Shaft of Femur.**—Dr. Elliott presented a five months old baby sent to him three weeks previously for diagnosis. He found dislocation of left hip and suspected fracture both of which were confirmed by X-ray picture. According to the history, birth of the child had been very difficult—the breech had presented and great difficulty had been experienced and instruments used. No difficulty was anticipated in reducing the dislocation; the fracture of the femur, however, complicated the matter. He said he proposed to attempt reduction under an anaesthetic and if any great difficulty presented itself, wait till later and do it by the Lorenz non-cutting method. **Congenital Dislocation of the Patella.** Dr. Elliott showed a patient a young man 20 years old with dislocation of the right patella. His relatives had told him that it was first noticed two days after his birth; he wore apparatus at various times but nothing since 1838. The patella slipped into place on extension but on flexion slid over the external condyle of the femur even if force was applied to hold it; there was two inches of atrophy of the right thigh; a slight degree of knock knee existed. All that the patient complained of was a sense of weakness and uncertainty of the leg. The patient wanted to know if the condition could be remedied without leaving him with a stiff knee. He preferred his present condition of slight disability to a stiff leg. **A Case of Spondylolisthesis.** Dr. Taylor presented a man 19 years old whose occupation was loading and unloading furniture. Last December he sought treatment for weakness of his back and occasional pains in the lumbar region at night, after hard work. About three years ago he slipped on the ice and fell heavily on the buttocks. He worked the following day. He experienced no inconvenience for sometime but within a few weeks he noticed a decided projection, lower part of spine, which he still has. He thinks it is less now than formerly. Examination revealed a marked projection of the fifth lumbar spine and a deep depression above it. At the bottom of this depression could be felt the fourth lumbar vertebral spine one-half inch in front of its normal position. The patient could bend forward and touch the floor and showed none of the characteristic attitudes of the rigidity of spondylitic. He was strong and able to work.

There were no rectal or bladder symptoms of lower extremity paralysis. Dr. A. E. Gallant showed a model of the triangular pasteboard Van Arsdale splint. He stated that this splint was used in children in fractured femur with excellent results; he had reported 33 cases himself. It was light, could be adjusted, leaving the child in a comfortable position and in young infants it was out of the way of soiling. The children were not confined to bed but could sit up and play without hindrance. He cut a model and drew a diagram illustrating the manner of preparing the splint.

Dr. William Jay Youmans.—Dr. Wm. Jay Youmans, for many years editor of *Popular Science Monthly*, to-day died at his home, in Mt. Vernon, N. Y., a suburb of this city, of typhoid fever, after an illness of ten days. When difficulties a year ago came upon the house of Appleton, and the *Science Monthly* was transferred, Dr. Youmans severed his connection with it, and retired permanently from active life. He was deeply attached to a handsome farm possessed by him among the hills near Saratoga, N. Y., where he was born, October 14, 1838, and near which he began his education in a district school. Dr. Youmans studied chemistry with his brother, Edward Livingston Youmans, at Columbia College and at Yale Scientific School. He graduated in medicine from New York University in 1865.

NEW ENGLAND.

Surgical Instruments Taxed.—Judge Colt, in the United States Circuit Court yesterday, dismissed the petition brought by the Massachusetts General Hospital for a review view of the decision of the Board of General Appraisers, holding that a case of imported surgical instruments was not entitled to exemption from duty under par. 638 of the Dingley Tariff Act. The goods are dutiable at 60 per cent. under the act. The instruments were for use in the hospital.

WESTERN STATES.

Dr. William F. McClelland Dead.—Dr. William F. McClelland, the first physician to make a study of the climatic influences of the mountain region upon pulmonary diseases, and who was widely known in America and Europe, through the performance of many difficult surgical operations, is dead at his home in Denver, Colorado, aged 80 years.

The St. Paul Meeting and Yellowstone Park.—Arrangements have been completed for an excursion of the members of the American Medical Association to Yellowstone Park. The Committee of Arrangements has finally succeeded in persuading the officials to open up the park a week earlier than usual in order to accommodate the association. A special train will be run from St. Paul to the Yellowstone Park and the railroad officials have promised to do everything in their power to make it satisfactory to all concerned. The rates will be very low, but how low can not at this time be definitely stated. Those who attended the meeting in 1882 will remember with much pleasure a similar excursion that was run at that time, and these will not need to be informed that the one now proposed will be full of enjoyment. Further announcements will be made later. The Yellowstone National Park contains more natural wonders than are to be found anywhere else in the world, and this will be a rare opportunity for our Eastern friends to see what this portion of our Great West possesses.

SOUTHERN STATES.

Tennessee State Medical Society.—At the sixty-eighth annual meeting of the Tennessee State Medical Society the following officers were elected: Deering J. Roberts, M. D. (Southern Practitioner), Nashville, president; J. B. Murfree, Jr., M. D. Murfreesboro, L. A. Yarborough, M. D., Covington, W. B. St. John, M. D., Bristol, vice-presidents; A. B. Cooke, M. D. Nashville, secretary; W. C. Bilbro, M. D., Murfreesboro, treasurer. Next place of meeting, Memphis, Tenn., on the second Tuesday in April, 1902.

Georgia Pasteur Institute.—The Board of Governors of the Pasteur Institute Laboratory met in Atlanta April 12th

to receive the first semi-annual report of the physician, Dr. Jas. N. Brawner and the pathologist, Dr. Claude C. Smith. Since December 1st, eleven cases have received the Pasteur treatment, and all dismissed as cured. Eight were bitten by rabid dogs as proved by inoculation of rabbits. The pathological department is doing good work also, and the Board was highly pleased with the first report.

To Investigate the Propagation of Yellow Fever.—The Orleans Parish (La.) Medical Society has appointed a special committee to study the mosquito as a means of propagating yellow fever.

North Carolina State Board of Medical Examiners.—The regular annual session of the North Carolina State Board of Medical Examiners will be held at Durham, N. C., beginning Thursday, May 16th, 1901.

The Orleans Parish Medical Society.—The Society passed resolutions urging the need of a City ordinance prohibiting spitting on the floors in public halls and public places of amusement. The sum of \$25.00 was donated to the \$1000 fund being raised in the United States as the contribution to the amount needed to erect a bronze statue of Prof. Ollier, in the City of Lyons, France. The members of the Society have additionally subscribed to the fund so that New Orleans will have added its full equivalent to the amount to be raised in this country.

The Inhalation of Menthol in Acute Inflammations of the Throat and Respiratory Tract.—Susdalsky (*Woenno-meditsinsky Journal*, Dec., 1900), employs inhalations of menthol in acute respiratory troubles with singular success. The cases reported by the author were all in soldiers. Recovery took place in about six days. The sooner the treatment was instituted the more rapid was the recovery. [A. R.]

Southern Idaho Medical Association.—The quarterly meeting of the Southern Idaho Medical Association was held April 4th. The next meeting will be held early in July at Shoshone. The following officers were elected: President, Dr. McCalla, Boise; vice-president, Dr. Ed. E. Maxey, Caldwell; secretary, Dr. H. A. Castle, Pocatello.

CANADA.

(From Our Special Correspondent.)

Hospital Work in Labrador was the theme of an address recently delivered in Montreal by Dr. W. T. Grenfell, who for the past eleven years has been superintendent of mission work among the fisher folk of that country. There are now three hospitals in Labrador. One is situated at Battle Harbor and another at Indian Harbor, whilst the third is in course of construction on the north French shore at St. Anthony. Besides these there is the hospital steamship, *Strathcona*, of which Dr. Grenfell is captain. This ship is provided with six beds and all necessary appliances, including the X-ray, and is constantly cruising up and down the coast. Dr. Grenfell is assisted in his work by two trained nurses, one a Canadian, and the other an Englishwoman, and men qualified in every way for the work. Last year the *Strathcona* attended to 1,020 cases, and there were sixty-two in-patients at Battle Harbor, and thirty-seven at Indian Harbor. Dr. T. D. Roddick, of Montreal, has given much assistance to Dr. Grenfell, especially this season when he came to Toronto and secured six physicians to accompany the sealing fleet last March, which was the first time in the history of the colony that these vessels had carried surgeons. Dr. Grenfell will return to Labrador in May.

Cremation in Quebec has been legalized by Act of Parliament. Some months back Sir William MacDonald, one of the leading of Montreal's philanthropic citizens, offered to erect at his own expense in the Mount Royal Cemetery, a crematory, providing the cemetery authorities would assume the cost of maintenance once the structure was raised and equipped. In order to carry out this project it was found to be necessary to have the consent of the Quebec Legislature, so a bill was introduced into that Assembly asking for powers to construct and conduct a crematory. From the very first this measure met with persistent and determined opposition, particularly from the Roman Catholic members of that body. With several

amendments the bill was finally gotten through that House by the narrow majority of one; and as Quebec province is governed by two houses of parliament, it then came before the upper house or the Legislative Council. As the bill stood then it provided that the "deceased had expressed a desire for cremation and that a certificate be produced that deceased at death was not a Roman Catholic." Before the Legislative Council the promoters of the bill objected to this amendment and stated that they did not desire to cremate Roman Catholics, but that they objected to any discrimination or exemption of any creed. In the Council, a motion to strike out the cremation clause resulted in a tie vote of eleven to eleven, and according to the rules of this body was lost, and as thus amended the bill became law, the amendment now standing: "That the deceased at the time of his death is entitled to be buried in Mount Royal Cemetery and has expressed by his will a wish that his body be cremated." On the 7th inst. Archbishop Bruchesi of Montreal issued a pastoral letter on the subject of the Delpit marriage and cremation, in which His Grace condemns the latter most strongly, stating that cremation is prohibited for all children of the church. This is the first legal recognition of the principal of cremation in the Dominion of Canada.

The Annual Report on Ontario Hospitals has just been issued. There are at present fifty or sixty of these institutions, situated in almost every town and city of any importance. That these are recognized by the people and are doing good work is evidenced in the largely increased population over that of the previous year. The hospitals at Sault Ste Marie and Parry Sound were added to the Government list for receiving annual grants. On the first of October, 1900 the number of patients remaining in the various hospitals of the province numbered 1,893, and the number of patients admitted during the year was 27,061. The number of deaths during the year was 1,451 and the number of days' stay in the hospitals was 739,816. The revenue from all sources other than the Government grant amounted to \$498,579.17; the provincial grant for the past year was \$110,000. The average cost per day per patient was 83½ cents. In addition to these institutions there are 100 charity homes, etc., in Ontario, having an aggregate population of 5,042. It costs \$234,602.53 to keep these up, of which the province contributes \$62,687.19.

Raising the Standard of Medical Matriculation at McGill will have become an accomplished fact after September 1902. At present candidates for admission into this faculty have to pass in English, mathematics and either French, German, Greek, chemistry or physics. After the date alluded to above they will all have to show that they are proficient in practical chemistry and possessing a sound, theoretical acquaintance with physics, statics and dynamics. The only optional subjects after that date will be French, German or Greek, of which one will have to be taken. Dr. Rutan, registrar of the faculty of medicine states that this will make the matriculation in the medical department of the University the most exacting of the departments. Some time ago the length of the regular sessions was increased from six to nine months for a four-year course; and more recently a combined arts and medical course was introduced. The present step will pave the way for a still further increase in the matriculation standard which will provide that all students contemplating the study of medicine at McGill will have to take a year's course in arts before being permitted to write on the medical matriculation. The change is calculated to prevent students from doing outside work while supposed to be working in the laboratories or attending lectures.

"Counter Prescribing" by Druggists in Toronto appears to be destined soon to be a thing of the past. Some little time ago a number of Toronto druggists appeared before the police magistrate charged with the offence. Convictions were registered in several cases on the charge of practicing medicine, and a fine of \$25 or thirty days in jail without hard labor given. From this judgment the druggists appealed to the County Court and had their appeal sustained and the decision of the magistrate's court reversed, but purely on a mere matter of form. Now several more are before the police magistrate who evidently holds strong views on this question. The other day when these cases were reached, the solicitor for the druggists moved that they be dismissed as the previous convictions

had not been sustained by the higher court. This the magistrate refused to do and delivered himself as follows: "A man committing an offence is nothing to making a mistake in a document.—I have a great deal of sympathy, too, with the poor people who go into drug stores for medicine, but when it is proved that a man says 'I am suffering' in such a way, and the druggist replies, 'Oh, you have indigestion,' or some other complaint, I will convict him and keep on convicting as many as are proved to have done this." "The Colonel," as the police magistrate is popularly called in Toronto, seems to have a proper idea of the fitness of things.

Society Notices.—The annual meeting of the Ontario Medical Association will be held in Toronto on the 19th and 20th of June, under the presidency of Dr. Angus McKinnon, of Guelph. Dr. Harold C. Parsons, Toronto, is the general secretary. The next annual meeting of the Canadian Medical Association will be held in Winnipeg on the 28th, 29th, 30th and 31st August. Dr. H. H. Chown of that city being the president and Dr. F. N. G. Starr, of Toronto, the general secretary.

MISCELLANY.

Photographing the Stomach.—It is stated that Drs. Lange and Melzing have succeeded in taking photographs of the mucous membrane of the stomach in the living subject. A stomach tube, sixty-six centimeters long, with a diameter of eleven millimeters is introduced, having at the lower end an electric lamp and at the upper end a camera. The stomach is first emptied and washed and then distended with air. Then fifty pictures can be taken in rapid succession in from ten to fifteen minutes. By turning the apparatus on its axis all parts of the mucous membrane can be pictured. The photographs are about the size of a cherry stone, but they can be enlarged to any extent.

A Bold Surgical Operation.—The *New York Tribune* quotes the story of a remarkable surgical operation told in a Danish medical periodical relative to the treatment of a patient who had become asphyxiated from the administration of chloroform. The operating surgeon was a certain Dr. Maag, but the method which he had employed had previously been suggested by Dr. Prus of Lemberg. A laborer, 27 years old, who had suffered from sciatica, was to be operated upon to relieve that trouble. Chloroform was given and the operation begun. The patient struggled, however, and when the process of anesthesia was carried further he stopped breathing. Several expedients were resorted to in order to restore respiration, but in vain. There was no longer any pulse. In this emergency Dr. Maag opened the chest, detached portions of the third and fourth ribs two and a half inches long, and turned them back with a flap of flesh. Through the opening thus made, he thrust his hand. The heart was firmly grasped and compressed rhythmically. After a few squeezes that organ began to beat naturally. It was necessary to employ compression again at times, and also to inflate the lungs artificially. But by these means the patient was kept alive for eleven hours and a half, and Dr. Maag is inclined to believe that the man would have recovered were it not that one of the pleura was accidentally punctured.

Yellow Fever in Jamaica.—Yellow fever has made its appearance at Port Royal, the entrance to Kingston, Ja. Two cases have been officially reported and one death has resulted. The health authorities are taking prompt measures, and with every prospect of success, to prevent the spread of the disease.

Medical Association Formed at Bangkok.—The *Hong Kong Telegraph* states that the medical men of Bangkok have formed a medical association. The aims of the association are the advancement of medical science and the protection of medical interests.

The Temple of Aesculapius.—Two years ago Dr. Rudolf Herzog, of Tuebingen, undertook excavations of the island of Cos with a view of finding the temple of Aesculapius. At a depth of eighty centimetres (thirty-two inches) he came upon a mosaic flooring which represented Orpheus charming the wild beasts. At a depth of two and a half metres (nearly eight feet), in the neighborhood of the church of St.

Anna, he found two columns, and not far from them the remains of an aqueduct and a small statue of a young man. Great importance is attached to Dr. Herzog's discovery of the supposed temple of Aesculapius. The excavations are still in progress, and it is hoped that many antiquities will be found.—*Medical Age*.

Dr. Chapot-Revost, the surgeon who operated for the separation of the Siamese twins, has gone to Vienna to study a case of Chinese twins similarly afflicted. The examination is to be made by means of Roentgen rays.

Ten Thousand Plague Victims in Six Weeks.—The United States consul at Canton, China, reports that 10,000 deaths from plague have occurred there during the past six weeks, and that there are thirteen cases of small pox on board the United States monitor Monterey. Only one death has resulted on the Monterey, and the other cases of smallpox are progressing favorably.

End of the Plague.—The sanitary report from Rio de Janeiro states the following: On February 20 there existed in the isolation hospital 3 patients, of whom 2 were discharged and 1 died on March 1. The last case of plague occurred February 17. Therefore, on March 9, the quarantine against Rio de Janeiro has been raised by the Brazilian Government and the disinfection stations and isolation hospital closed. The occurrences of plague since April 18, 1900, are as follows: Cases ascertained.—Patients received at the Paulo Candido Isolation Hospital: 1900—April, 7; May, 50; June, 136; July, 112; August, 72; September, 27; October, 29; November, 30; December 22. 1901—January, 11; February, 5. Total, 491. Cases confirmed at the residence of the patients: 1900—April, none; May, 11; June, 18; July, 30; August, 20; September, 4; October, 4; November, 6; December, 2. 1901—January, 3; February, none. Total, 98. Therefore, the total number of cases was 589. Deaths.—Patients who have died at the Paulo Candido Hospital: 1900—April, 2; May, 12; June, 55; July, 47; August, 30; September, 15; October, 15; November, 15; December, 10. 1901—January, 5; February, 4; March, 1. Total, 211. All the cases of plague confirmed at the residences of moribunds or deceased were 98, therefore the total number of deaths were 309 (52.5 per cent). Recoveries.—Patients who have removed at the Paulo Candido Hospital: 1900—April and May, none; June, 24; July 70; August, 70; September, 45; October, 23; November, 13; December, 16. 1901—January, 7; February, 12. Total, 280. Deaths.—The following is the report on patients: Nine were dead on reaching the hospital, 62 died within twenty-four hours, 34 died within forty-eight hours, and 106 died more than forty-eight hours after their arrival at the hospital.

Obituary.—Dr. S. C. Griswold, New Haven, Mo., on April 7, aged 68 years. Dr. James A. S. Carpenter, at Washington, D. C., on April 2, aged 74 years. Dr. William Fleet Luckett, at Washington, D. C., on March 30, aged 63 years. Dr. W. T. Hord, at Washington, D. C., on April 1. Dr. William N. Guernsey, at New York City, on April 9. Dr. John Ferguson, at Manchester, N. H., April, 1901. Dr. J. P. Dillard, at Martinsville, Va., on April 10th. Dr. James C. Larsh, at Washington, D. C., on April 3, aged 80 years.

Changes in the Medical Corps of the U. S. Navy, for the week ending April 6, 1901:

MAJ. CHARLES B. EWING, surgeon, now on duty at Santa Mesa Hospital, Manila, P. I., is detailed as a member of the board of medical officers appointed Jan. 16, 1900, for the purpose of studying tropical diseases as they occur in the Philippine Islands. H. Q. A., April 5.

FIRST LIEUT. CHARLES W. FARR, A. S., recently appointed, will proceed from Elmira, N. Y., to Fort Reno, for duty, to relieve Capt. Francis M. McCallum, A. S., who will proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., April 5.

CAPT. THOMAS C. LONGINO, A. S., will accompany troops G and H. 10th Cavalry, to San Francisco. S. O. 44, April 1, D. T.

ACT. ASST. SURG. WILLIS S. HORNE will proceed to Fort McIntosh and report to accompany troops E and F, 10th Cavalry, to San Francisco. S. O. 44, April 1, D. T.

ACT. ASST. SURG. NEVIL M. GARRETT will proceed to

the detention camp, Angel Island, Cal., for duty with companies K and L, 11th Infantry. S. O. 75, April 2, D. Cal.

ACT. ASST. SURG. FREDERICK H. MOHART having arrived on the transport Lagon, and now sick at the Army General Hospital, Presidio, will proceed to his home, Washington, D. C., when able to travel, for annulment of contract. S. O. 77, April 4, D. Cal.

CAPT. GEORGE J. NEWGARDEN, A. S., upon the expiration of leave granted him Feb. 27, will proceed to Fort Mason, for duty. H. O. A., April 8.

LIEUT. COL. CALVIN DE WITT, D. S. G., is relieved from further duty as chief surgeon, department of Dakota, and will report to the surgeon general of the Army for duty. H. Q. A., April 11.

ORDERS of April 5 are so amended as to direct Capt. Francis M. McCallum, A. C., upon his relief from duty at Fort Reno, to proceed via Jefferson Barracks to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., April 11.

ORDERS of April 1, relating to Capt. Frederick C. Jackson, A. S., are revoked. H. Q. A., April 11.

CAPT. FREDERICK C. JACKSON is granted leave for one month on surgeon's certificate. H. Q. A., April 11.

CAPT. FREDERICK C. JACKSON, A. S., will upon the expiration of the sick leave granted him April 11, proceed to Columbus Barracks, for temporary duty. H. Q. A., April 11.

CAPT. ALBERT H. EBER, A. S., recently appointed, is granted leave for one month. H. Q. A., April 11.

CAPT. ERNEST K. JOHNSTONE, A. S., recently appointed, now in San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., April 11.

CAPT. GEORGE B. LAWRASON, A. S., recently appointed, will proceed to San Francisco, Cal., for transportation to Manila, P. I., where he will report for assignment to duty. H. Q. A., April 11.

Official List of the Changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service for the 7 days ended April 11, 1901.

C. E. BANKS, surgeon, granted leave of absence for 6 days from April 15—April 11, 1901.

J. J. KINYOUN, surgeon, relieved from duty at San Francisco, Quarantine, and directed to proceed to Detroit, Michigan, and assume command of the service—April 6, 1901. Granted leave of absence for 15 days—April 11, 1901.

T. B. PERRY, surgeon, Department letter of March 2, 1901, granting Surgeon Perry leave of absence for 30 days, amended so that said leave shall be for 20 days—April 5, 1901.

J. B. GREENE, passed assistant surgeon, relieved from duty at Berlin, Germany, and directed to proceed to Washington, D. C.—April 5, 1901.

L. E. COFER, passed assistant surgeon, designated as Chief Quarantine Officer of the Territory of Hawaii, relieving Surgeon D. A. Carmichael—April 6, 1901.

HILL HASTINGS, assistant surgeon, to proceed to Santa Barbara, Cal., for special temporary duty—April 6, 1901.

C. H. LAVINDER, assistant surgeon, Beaureau telegram, granting Assistant Surgeon Lavinder leave of absence for 10 days, amended so that said leave shall begin April 1st instead of March 27—April 5, 1901.

S. B. GRUBBS, assistant surgeon, granted leave of absence for 7 days—April 10, 1901. Upon expiration of leave to proceed to Washington, D. C., and report at Bureau for duty—April 10, 1901.

L. L. LUMSDEN, assistant surgeon, upon departure of Surgeon J. Kinyoun, to assume temporary command of San Francisco quarantine station—April 6, 1901.

EDWARD FRANCIS, assistant surgeon, to proceed to New York, and report to medical officer in command, Immigration Depot, for duty—April 8, 1901.

G. H. ALTREE, acting assistant surgeon, granted leave of absence for 4 days from April 10—April 6, 1901.

HENRY GAHN, hospital steward and chemist, to assume temporary charge of Purveying Depot during absence of Medical Purveyor—April 8, 1901.

F. L. BROWN, hospital steward, relieved from duty at Boston, Mass., and directed to proceed to Cape Charles Quarantine station and report to medical officer in command for duty and assignment to quarters—April 10, 1901.

F. H. PECK, hospital steward, to proceed to San Francisco, Cal., for special temporary duty—April 5, 1901.

PROMOTION.

ASST. SURG. H. S. MATHEWSON promoted and appointed passed assistant surgeon to rank as such from as such from April 7—April 6, 1901.

APPOINTMENT.

J. A. MONCURE reinstated and appointed acting assistant surgeon, U. S. Marine Hospital Service, for duty at the Gulf quarantine station—March 29, 1901.

Changes in the Medical Corps of the Navy for the week ending April 13.

MEDICAL DIRECTOR W. K. SCHOFIELD, detached from duty at Philadelphia, April 27, and ordered here to wait orders.

MEDICAL DIRECTOR W. O. FARWELL, detached from Navy Yard, League Island, and to Special Duty in Philadelphia.

SURGEON C. BIDDLE, ordered to Philadelphia Navy Yard, as the relief of Medical Director W. C. Farwell.

SURGEON G. H. GRIFFITH, ordered to temporary duty in charge of the exhibit of Bureau of Medicine and Surgery at the Pan-American Exposition, Buffalo, April 27th.

ASST. SURGEON R. B. WILLIAMS, detached from Navy Yard, Pensacola, and ordered to Key West Naval Station with temporary duty to Dry Tortugas, with detachment of marines.

MEDICAL INSPECTOR J. E. WAGGENER, detached from duty at Naval Hospital, Cavite, and to Naval Hospital, Mare Island, having been condemned by Board of Medical Survey.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended April 12, 1901:

SMALLPOX—UNITED STATES.

			Cases.	Deaths

GREAT BRITAIN.

London's Contribution.—The Court of Common Council of the City of London have agreed to contribute the sum of 100 guineas out of the city's cash towards the purposes of the forthcoming Congress on Tuberculosis, to be held in London.

Gallantry and Devotion of an Army Surgeon.—The King has conferred the Victoria Cross on Lieutenant H. E. M. Douglas, of the Royal Army Medical Corps, for special gallantry and devotion during the action at Magersfontein on December 11th, 1899. Under a very severe fire, says the *Gazette*, Lieutenant Douglas advanced in the open and attended Captain Gordon, of the Gordon Highlanders, who was wounded, and also attended to Major Robinson and other wounded men under a fearful fire.

University of South Wales.—Mr. Alfred Thomas, M. P., has been elected President of the University College of South Wales in succession to Lord Tredegar, who has held the office during the last five years, and who is debarred by statute from re-election.

Memorial Hospital at Cairo to Queen Victoria.—Lord

Cromer, the British diplomatic agent in Egypt, and John G. Long, United States Consul-General in Cairo, jointly presided on March 8th at an Anglo-American meeting to consider a memorial to Queen Victoria. Both delivered addresses advocating the founding of an Anglo-American hospital, which suggestion was approved by the meeting. Sir Ernest Cassel subscribed £1,000 to the memorial fund, and the subscriptions altogether reached a total of £10,000.

CONTINENTAL EUROPE.

Physicians of the Royal Family of Spain.—Dr. Vincente Llorente, one of the leading physicians in Madrid, has been appointed to fill the vacancy of Physician to the Royal Family of Spain caused by the death of Dr. Olavide.

Dr. Samuel Pozi.—Dr. Samuel Pozi has been appointed Professor of Clinical Gynecology in the University of Paris. He is a member of the French Senate, and was one of the most eminent foreigners on whom an honorary fellowship was conferred by the Royal College of Surgeons at its centenary celebration.

St. Bartholomew's Hospital.—The vacancy for the post of ophthalmic surgeon to St. Bartholomew's Hospital caused by the death of Mr. Bowater John Vernon has been filled by the election of Mr. Holmes Spicer. Mr. W. H. Jessup becomes senior ophthalmic surgeon in place of Mr. Vernon, with the appointment of lecturer in ophthalmic medicine and surgery.

Smallpox Diminishing.—The smallpox epidemic at Glasgow continues to diminish, the number of new cases occurring daily being very much less and the officials take a more hopeful view of the situation. On March 15 there were 405 cases in hospital, while on March 22 there were only 380 cases. The improvement is attributed to revaccination, which has been urged upon the people, and it is asserted that no case has occurred among those who have been successfully revaccinated. No further cases have been reported in Edinburgh, so the total for that town remains at 5 cases and 1 death. There was 1 case of smallpox under treatment in the London fever hospital for the week ended March 16.

Strike of Physicians at Leipsic.—At Leipsic one hundred and fifty-five municipal physicians have gone on strike for higher pay and more considerate treatment.

Assistant Physicians in the St. Petersburg Hospital Placed on a Salary.—The city council appointed 15 assistant physicians to the various city hospitals on an aggregate salary of 10,800 roubles (about 5,400 dollars). The salaries of the chiefs were also increased.

An Emergency Medical Society.—In Kieff a medical society is being formed with the object of attending to emergency cases.

Death of Professor Joseph Von Fodor.—With the death of Professor Von Pettenkofer still fresh in our minds, we regret that we have to announce the death of Prof. Josef Von Fodor. He was born at Lakosca, Hungary, on July 16, 1843. He studied medicine at Buda-Pesth, Munich and Vienna and graduated as Doctor of Medicine from the University of Buda-Pesth in 1865. In 1866 he was appointed Assistant to the Chair of State Medicine at Buda-Pesth. In 1870 he went to Munich and studied under Pettenkofer and Liebig. His first publication was a monograph on Sanitary Administration in England, which appeared in 1873 and was crowned by the Hungarian Academy of Science. His greatest work is his *Hygienischen Untersuchungen über Luft, Boden und Wasser*, (Hygienic Researches on Air, Soil and Water), in two volumes, which was published in 1881 and 1882. Among his other writings are addresses and papers—most of which were published in the *Vierteljahrsschrift für öffentliche Gesundheitspflege* and the *Archiv für Hygiene*—on soil and soil gases (1875), healthy dwellings (1878), the condition of longevity (1885), the bactericidal action of the blood and immunisation (1890), immunisation by alkalisation (1891), water supply, drainage, typhoid fever, and drinking water, etc. Professor von Fodor was also the author of a textbook of hygiene for schools which appeared in 1887; a second edition was published in 1892. The *British Medical Journal* publishes the personal reminiscences of one of his dearest friends, concerning him.

1.—Barrs is of the opinion that there is no practical utility from a therapeutic or prognostic point of view in distinguishing between a large white and a small red kidney, even if it could be done with any certainty. The one point in this connection that requires determination is whether the condition is chronic or acute. For, upon its not being the former and being the latter depend such chances as the patient has of recovery. The author has rarely seen a case of **chronic Bright's disease** in which there is a history, first, of acute nephritis, then of an interval more or less prolonged in which the symptoms fall into abeyance, and then of a chronic persistent condition lasting for years, it may be, and ending in death. He has believed and taught for a long time that acute nephritis has much the same definite march, though usually over a much longer period of time, as acute pneumonia, and ending in complete recovery or death in due course. We much more frequently see acute nephritis associated with longstanding latent renal disease than we see chronic nephritis directly traced to an acute attack. The etiology of the disease according to the author's views is not satisfactorily explained by the prevailing theories. Lead as a cause of chronic nephritis he can understand; but he is of the opinion that alcohol has little to do with its causation. He is in doubt whether the causative relation of gout to chronic renal disease is so frequent as is commonly believed. He inclines to the idea of a bacterial origin of the chronic inflammatory destructions of the kidney. A diagnosis of chronic Bright's disease in the absence of albuminuria cannot safely be made. The idea of chronic Bright's disease without albuminuria is based largely, if not entirely, upon post-mortem room experience. Those who have done much post-mortem room work know how common it is to find kidneys that do not conform in every particular to normal standards. The author does not say that the kidney condition is not answerable for the patient's death, but he insists that such a condition is not Bright's disease in the strict and clinical sense of the term; and that it cannot be recognized during life. Clinically, the quantitative estimation of albumin is of no importance whatever, nor is the estimation of urea of any great value. Urines of persistently low specific gravity without albuminuria are said to indicate chronic Bright's disease, yet this is not, in the opinion of the writer, not a reliable indication. No urine need be searched for the tube casts which does not contain albumin. There is great uncertainty in the association of renal with circulatory disease. Arteriosclerosis, altogether independent of renal disease, is a far more common cause of cardiac hypertrophy than Bright's disease; and vascular disease of this nature is probably a cause as well as a result of renal disease. Chronic renal disease has such a common association with cerebral hemorrhage as has been supposed. Speaking of diet in chronic nephritis the author advances the opinion that to live for weeks and weeks on a purely milk diet is not, in many cases, necessary, and in some cases it is distinctly harmful, and there is no clear evidence that it meets the scientific indication. His

rule is that if the bowels are acting freely, the patient may live on such ordinary mixed diet, including meat, as he has an appetite for and can digest. Patients who are confined to bed and suffering from uremic vomiting or diarrhea and are, therefore, getting toward the end of the disease cannot, of course, have any appetite, and the difficulty is to contrive food of any kind for them. Of the many drugs which are in use in the treatment of Bright's disease, some are of great value. But the systematic use of purgatives is not approved of because he has no great faith in the so-called vicarious actions of organs. Diuretics such as digitalis are frequently of the greatest use and almost as frequently fail. Diaphoretic drugs—and of these pilocarpin is the only really active one—are sometimes unpleasant, not to say dangerous in their effects; and the hot bath and hot air bath do all that can be done, and are strictly under our control. Vasodilators have very little, if any, diuretic action in chronic Bright's disease, but in dyspnea, headache, and vomiting frequently give great relief. The nervous and respiratory disturbances of the more severe degree of renal toxemia, which usually portend a not far distant death may be treated by bleeding, purging, and sweating. Morphine can be given with perfect safety sometimes. [J. M. S.]

2.—After a study of gonorrhea, Ward advances the following tests to account for the occurrence of **general infection**. The gonococcus in its process of growth in the human body produces an irritating toxin. This toxin is the direct cause of all the symptoms of the disease. In all cases it is absorbed into the system, where its presence causes systemic degeneration of varying degrees of severity. **Gonorrhea** is thus a general toxicemic affection; but the microorganisms that form the toxin are generally localized on or around a mucous tract. The microorganisms may extend to the organs communicating with the infected tract, or it may penetrate into the tissues, either by direct extension, as in the invasion of the peritoneum through the uterus and oviducts, or by a process of growth through the mucous membrane affected. Thence the infection may invade the cellular tissues, the lymphatics and glands, and the vascular system. This invasion is rendered possible by the action of the absorbed toxin upon the leukocytes, which is of a paralyzing nature, and prevents the encapsulation of the microorganisms by these cells. Having reached the circulation the gonococci may invade the heart and endocardium, or may be carried to the peripheral capillaries. In these they become stranded and grow, producing more toxin, which sets up local inflammations. The microorganisms invade the joints, and are found in the synovial sacs, and also in the pleura and pericardium. They are probably present in the analogous inflammations of the tendons and periosteum. The invasion of the organism is favored by all too energetic measures directed to the local infection, since they depress the local powers of resistance, and by abrading or lacerating the mucous surface, may directly open the door to the invasion. General treatment must vary according to the general conditions, and will differ when these are referred to toxemia alone, or to toxemia complicated by metastasis. Local treatment is always required, and should always be free from instrumental, mechanical, or chemical violence. [J. M. S.]

3.—Rolleston and Hayne report the case of a male child, aged 6 months, who had been jaundiced since birth. A fortnight before death the jaundice became more marked. The liver was found to extend to the anterior superior spine of the ilium. The spleen was also enlarged and projected 3 finger breadths below the costal arch. There was no ascites. The urine was bile-stained, and the motions clay-colored. Just before death the temperature rose to 102°, and an attack of hemoptysis occurred. At autopsy it was found that the liver was nearly twice the normal weight, yellow in color, and manifestly cirrhotic. The common bile duct was small, and at its lower end it was transformed into a slender fibrous cord. The gall bladder was small, thickened, collapsed, and buried in adhesions; the cystic duct was represented by a thin fibrous cord. There were enlarged glands in the portal system, suggesting the condition found in hypertrophic biliary cirrhosis. Microscopic examination of the liver showed that fibrosis was everywhere present. The case is one of congenital hepatic cirrhosis with obliterative cholangitis. The following hypothesis appears to be a reasonable explanation of the pathology of so-called **congenital obliteration of the**

bile ducts: In the first instance, poisons pass by the blood from the placenta to the fetus by the umbilical vein some of this blood at once passes through the liver and, in virtue of the toxic effect of the contained body or bodies, induces ordinary portal or multibular cirrhosis of the liver; the remainder of the blood in the umbilical vein passes directly into the general circulation of the fetus by the ductus venosus, and subsequently, by means of the hepatic artery, will convey poison to the liver. By this means the toxic body which may be analogous to toluyendiamine is excreted into the small intrahepatic bile ducts, setting up cholangitis and monolobblar cirrhosis. In this way a mixed cirrhosis, portal and biliary, is induced. The cholangitis descends to the larger ducts, and gives rise to an obliterative appendicitis. The difference between this condition of congenital cirrhosis with obliterative cholangitis and other forms of cirrhosis in post-natal life consists in the further change in the large bile ducts and gall bladder. An attempt to explain this additional lesion may be made as follows: The bile ducts are extremely small at birth, and any inflammatory change will, from the small size of the lumen, produce stenosis much more readily than later in life. [J. M. S.]

4.—Williamson reports a case in which sodium salicylate had a definite influence in greatly diminishing the sugar excretion in diabetes. Other conditions, being kept the same, when the drug was given in large doses, the sugar excretion greatly diminished; when the drug was discontinued the sugar excretion at once increased rapidly; and when the drug was again given the sugar excretion greatly diminished. A report of 19 other cases of diabetes or persistent glycosuria in which sodium salicylate was used is also published. It is not advisable to give sodium salicylate if serious complications are present, or if the patient appears to be losing ground rapidly, because the drug has a bad reputation with many practitioners, and a fatal termination during the salicylate treatment is liable to be attributed to the drug. The author does not regard sodium salicylate as a specific for diabetes. It does not usually produce any marked diminution of the sugar excretion in the severe forms of the disease; also it has little influence in some of the mild cases.

But in certain cases of diabetes or persistent glycosuria it has a decided action in very markedly diminishing the sugar excretion. It requires to be very carefully watched, and fairly large doses are usually necessary to produce decided results. It is best to commence with 10 grs. 3 and then 4 times a day, and to increase slowly up to 15 grs. 4 or 5 times a day, watching carefully for any toxic symptoms. [J. M. S.]

5.—Freeland Fergus described an easy operation for congenital ptosis. A horizontal linear incision is made in the eyebrow so that the hairs of the eyebrow will subsequently hide the scar. After separating the skin from the underlying structures the skin is separated for a distance of about 2 inches above; below, the skin fascia and some of the muscular structure are separated from the tarsus, almost to the extreme margin of the lid. A vertical band of the tendon and fascia of the occipito-frontalis muscle two inches long and about three-quarters of an inch broad, is dissected up until the only attachment of a band is to that portion of the occipito-frontalis muscle furthest away from the original incision. The end of the band is then drawn down into the upper lid and its margin fastened by catgut sutures as near the margin of the lid as possible. The skin wound is closed and covered with a sterile dressing. [M. R. D.]

6.—John Thompson discusses the peculiar nystagmus of spasm nutans in infants. He states that the existence of a convergent form of nystagmus is not generally recognized even in large and recent works of ophthalmology, nor in books on diseases of children. He believes it to be a co-ordination-neurosis, and that it develops in the months during which the child is learning to co-ordinate the movements of the eye with those of the head. The nystagmus of spasmus nutans is often unilateral as well as verticle and rotary, and is invariably recovered from within a few months. [M. R. D.]

7.—McCaw reports the case of a child aged 13 days who was suffering from tetanus neonatorum. The treatment was begun by the subcutaneous injection of 5 c.c.m. of tetanus antitoxin, and this was followed, 2 days later, by 2½ c. cm. om antitoxin. The progress of the case was

entirely satisfactory. Bacterial examination of the discharge from a sloughing surface at the umbilicus showed plentiful growth of bacilli having the characters of the tetanus bacilli. There were also some streptococci. [J. M. S.]

8.—Gordon calls attention to a condition of the knee-jerk in chorea which, although not present in every case and is not constantly present in the same case, is peculiar to the disease. With the patient recumbent, if one raises the knee, allowing the heel to rest on the couch, making sure that all the muscles of the limbs are relaxed for the time being, and if one then tests the knee-jerk in the usual way, the foot is found to rise more or less smartly, but, instead of falling back immediately, it remains suspended for a variable time—hung up as it were—and then slowly sinks back to its initial position. The author believes that the sign has some value in the diagnosis of slight and doubtful cases. He has never once seen it. [J. M. S.]

9.—Blackadder reports the case of a boy, aged 8 weeks, who was admitted to the hospital for wasting and vomiting. The first symptom that attracted the mother's attention was extreme constipation. Usually there was no movement of the bowels for 3 days at a time. When the child was a fortnight old it began to vomit after every feeding. Occasionally there was no vomiting for 1 or 2 days; then it vomited a large quantity at once. There were no physical signs of a dilated stomach, nor was any tumor palpable. Post-mortem examination showed a sausage-shaped thickening of cartilaginous consistence in the pyloric region ¾ inches in length. No fluid could be seen to flow through the stenosed orifice. The case was one of congenital hypertrophy with stenosis of the pylorus. [J. M. S.]

LANCET.

March 30th, 1901.

7. "Selenium Compounds as Factors in the Recent Beer-Poisoning Epidemic." F. W. TUNNICLIFFE and OTTO ROSENHEIM.
8. The Management of Home Military Hospitals. SURG.-CAPTAIN W. PUGIN THORNTON.

1.—Addison, in continuing his lecture on the topographical anatomy of the abdominal viscera, discusses first the lateral displacements of the pylorus and next the movements of the stomach and its relation in these various positions to the other abdominal viscera. The influence of the stomach upon the shape and position of the parts behind it is then spoken of. The various positions and relations of the duodenum and small intestine are next mentioned. In beginning with the peritoneum Addison mentions prolapse of the mesentery. In these cases the mesentery is attached much lower than is normal. [J. H. G.]

2.—Hewitt thinks that the method of producing anesthesia introduced by Clover, which consists in administering first nitrous oxide and then ether, is far superior to any other method which we possess at the present time. By Clover's method of etherization there are two factors at play, first the ether, and second a certain amount of asphyxia. The latter is brought about by permitting a very small ingress of oxygen, the effect of which is to make the anaesthesia much more profound. Hewitt uses an inhaler, the tubes of which are of much larger calibre than those of the Clover apparatus, and this difference he maintains, eliminates to a great extent the stertor and cyanosis which accompanies the administration of nitrous oxide and ether. He considers deep and obstructive stertor

to be a danger signal and an indication for the need of oxygen. The dorsal position with the face looking upwards is an improper position for any form of anaesthesia; the head should be turned to one side. The patient is allowed first to breathe the nitrous oxide until partly under the effect of this gas, and then the ether reservoir is filled. Attention is then called to the successful use of gas, ether and chloroform in producing anaesthesia. Gas for the patient, ether for the anaesthetist, and chloroform for the surgeon. Nitrous oxide is pleasanter for the patient to take, ether can be given with safety and has a stimulating action on the respiration and circulation, and chloroform is of advantage because of the quiet of the patient and the comparative freedom from venous engorgement. The danger of chloroform is during the second stage of anaesthesia, that is, the stage of excitement. With the administration first of nitrous oxide and then ether, this danger stage is avoided. The disagreeable after effects from the prolonged use of ether can also be avoided by this combination. Hewitt thinks this method far superior to any other in producing anaesthesia. The change from ether to chloroform should never be made while the patient is struggling, nor should the change be made when the patient is profoundly under the influence of ether. It is better to allow the patient to recover sufficiently from the ether to cough slightly, which frees the larynx of any mucus, and then to begin the use of the chloroform. This method of anaesthesia is particularly to be recommended in operations about the mouth, throat and nose, and in such cases the Junker inhaler is used. Hewitt then describes what he calls a chloroform-prop, which serves the purpose of keeping the mouth gagged open, and having in addition a hollow tube attached to it, which allows the inhalation of the chloroform without interference with the work of the surgeon. [J. H. G.]

3.—Buchnall reports six cases of separation of the epiphyses of the humerus and radius. In the first examination of all the injuries about elbow joint in young people he strongly urges the necessity of the use of a general anaesthetic in order that the exact condition may be known. He finds that a molded gutta-percha splint is more satisfactory in these cases than a splint of wood or metal. In most of the cases an injury to the elbow joint the arm was dressed in a flexed position. Buchnall urges the importance of early passive motion in these fractures in order to prevent adhesion and limitation of motion. This is usually begun about the 10th day and increased each day, the separated portion of the bone being held firmly with the hand. If a separated epiphysis has been allowed to go without treatment and no union has taken place, it is oftentimes better to remove it. A separation of the internal condyle of the humerus will frequently produce an ulnar palsy, which is illustrated in one of the cases reported. [J. H. G.]

4.—Walsham speaks of the great difficulty in overcoming the obstruction of free inspiration due to collapse of the ala nasi. He urges the careful observance of this condition as an obstruction, and thinks that it is frequently overlooked. He has found drainage tubes, celluloid expanders, and the various rings recommended for the condition all unsatisfactory and discomforting to the patient. For the relief of this condition he has devised a plastic operation which consists in placing a flap of mucous membrane rolled upon itself into the anterior space between the ala and the septum, and fixing it here by means of a suture. This offers sufficient obstruction to prevent the collapse of the ala. [J. H. G.]

6.—Jakins reports a case of a man who had suffered from middle ear disease for two years. Five months before admission a polypus was removed. This had no effect upon the discharge, which continued as before, but on admission the patient complained of severe pain all over the right side of the head, the right mastoid was tender on pressure and there was marked giddiness and nausea; the complexion was pale, the breath offensive and the lips and teeth covered with sordes. The meatal canal was found full of offensive pus and there was distinct bulging of the superior and posterior meatal walls. On the next day the mastoid antrum was opened and found to contain granulation tissue and cholesteatoma, and a communication was found in the middle fossa, exposing the dura mater. The temporal muscle was then reflected and a portion

of bone removed by the trephine, but as no bulging was found exploration of the cerebrum was not made. After the operation the patient was greatly relieved, but in three days he complained of a great deal of pain, became very restless, which was followed by a comatose condition and a palsy of the left leg and arm. The trephine opening was again exposed, the dura mater was found to bulge, and when it was divided and a grooved director was passed into the temporo-sphenoidal lobe, a quantity of foul smelling pus escaped, the cavity was drained and the patient made a good recovery. The palsy of the arm and leg disappeared very promptly. Jakins thinks that the presence of a polyp or granulation tissue in the extreme canal indicates trouble in the antrum or attic or both, and that the removal of the growth through the external meatus is of no advantage. Within two years he has operated upon four cases of cerebral abscess caused by middle ear disease. [J. H. G.]

5.—Newman describes the treatment of arthritis deformans and sclerodema by super-heated dry air (Tallerman System). The author states that two different forms of the apparatus are used: (1) for the pelvis; and (2) for the extremities. The temperature in the apparatus is raised to 300° F. The portion of the body subjected to the heat is wrapped in a covering of woven asbestos. On account of the profuse perspiration which occurs during the course of treatment, the patient must be undressed and clad in a loose wrap. A feeling of moderate warmth is experienced in the part subjected to the heat. The intense heat never produces a sensation of discomfort. During the treatment the pulse rate increases from 10 to 20 beats per minute, and the bodily temperature rises scarcely more than ½° Celsius; albuminuria has never been produced by this treatment. The author believes that super-heated dry air will come into more general use as a therapeutic agent, and from his own experience he has never seen any ill effects either on the local seat or upon the system. He has applied this plan of treatment in a large number of cases: chiefly rheumatic neuritis, chorea, gout, chronic rheumatism, rheumatic arthritis, stiff and swollen joints, sprains and ruptures of the joints, fractures and inflamed flat foot. During the last year he has applied the treatment of 70 cases of sciatica, 35 cases of arthritis deformans; also in chronic arthritic rheumatism, badly mended fractures with interruption of the circulation, severe sprains of the pelvis and spine, painful cicatrices and contraction after gunshot wounds, in three cases of sclerodema, one case of myxodema and in cases of inflamed flat-foot. In three cases of sciatica no result whatever was obtained; doubtful results were obtained in two cases of arthritis deformans. In two cases of apparently old fracture of the neck and of the femur, with severe contusions of the pelvis, there was no improvement. The treatment was not successful in a case of inflamed flat foot, and in a case of scleroderma, but all of the remaining cases showed marked improvement and some were completely cured. The author of a number of cases of sciatica and arthritis deformans, one case of scleroderma and one of myxodema. [F. J. K.]

7.—Tunncliffe and Rosenheim state that they have found selenium in an invert sugar used in brewing. They had previously found selenium in beer, and they conclude "that selenium compounds have played a definite role in the recent beer poisoning epidemic, their part being, however, subsidiary to arsenic." In some of the beer examined these observers found selenium dioxide in amounts equal to one-third or three-fourths of that of arsenic. [F. J. K.]

8.

THE NEW YORK MEDICAL JOURNAL.

April 13, 1901. Vol. LXXIII, No. 15.)

1. German Text-books Half a Century ago; History and Reminiscences. A. JACOBI.
2. A Shielded Piston Syringe for Urethral and Vesical Irrigation. RILUS EASTMAN.
3. The Correction of the Deviations of the Nasal Septum, with Special Reference to the Use of the Author's Fenestrated Comminuting Forceps. JOHN O. ROE.
4. The Pathology of Intra-uterine Death. NEIL MACPHATTER.
5. The Preponderance of Male Stammerers over Females. DAVID GREENE.

6. The Management of Gonorrhea. BOLESŁAW LAPOWSKI.

2.—Eastman advises for irrigating the most simple apparatus, and uses one consisting of a five-ounce metallic syringe with detachable blunt nozzle. A thin-spun metal shield surrounds the barrel. The shield is made movable, in order that it may be held up while the nozzle is introduced into a vessel for filling. His reasons for using so simple a syringe are: (1.) It is easily and entirely sterilizable; (2.) The solution is taken from the top of a column of liquid, as, for example, in a large graduate, the crystals that may be present in the bottom of the receptacle are not taken up; (3.) With the piston syringe the pressure exerted may be finely gauged by the resistance against the operator's thumb pressing the piston; (4.) The force of the current may be instantaneously lessened or the stream entirely cut off; (5.) The use of the instrument is attended with no inconvenience or loss of time; (6.) It is easily transportable; (7.) It is simple in construction and application. (T. M. T.)

3.—Roe briefly summarizes the special advantages that can be claimed for the superiority of the method which he describes over other methods for the correction of the various deviations of the septum: (1) The facility and ease with which, in every instance, the osseous and osseocartilaginous portion of the septum can be fractured and all resistance removed without incising or even lacerating the septum, may be noted; (2) By fracturing the anterior portion of the osseous septum and changing its direction by putting it in a straight line together with the cartilaginous portion, so that, when this osseous portion becomes reunited in its new position and firm ossification has taken place, the cartilaginous portion is firmly held in its new position. As osseous tissues does not readily bend, this must necessarily act as a firm post or support to hold the cartilage in its new position, very much in the same manner as the direction of the hang of a door is changed at its hinges; (3) Moderate deflection of the cartilaginous portion of the septum can also be fractured with the forceps and the elasticity overcome, without the necessity of incising the cartilage; (4) By this instrument, wrinkles and curves can very readily be smoothed out, no additional operative measures being required, except for the removal of spurs and ridges or the breaking up of adhesions or attachments that may have previously formed; (5) By this method, dislocations of the latter at its auxiliary attachment, can very readily be reduced and the parts put in their normal position. By this method, also, except in rare cases, the extensive incisions proposed by different operators are obviated; such as crucial or rectangular incisions with cutting forceps; the horseshoe incisions through which the deflected portion is pushed, which cannot be of special service except in limited indented deviations of the triangular cartilage, or the separation and setting over of the base of the setum into the free nostril far enough to leave both nasal passages of equal calibre which simply compensates for the bend in the septum without straightening it after all; (6) In those cases in which incision through the cartilage is required to provide for the redundancy, the superiority of the oblique incision, which promotes coaptation of the cut out surfaces, over the right-angled incision, which does not is at once apparent; (7) The superiority of the fenestrated forceps over the flat-bladed forceps or the fingers, as proposed by some operators, for breaking up the base of the fragments at their bony attachments, thus endangering brain complications, and by completely removing the elasticity of the attachments of the deflected parts, it facilitates the more ready adjustment of the septum to its normal position and diminishes the length of support to the septum is required. [T. M. T.]

MEDICAL RECORD.

1. Remarks on Enteroptosis. MAX EINHORN.
2. Small Hospitals and Their Administration. LOUIS N. LANEHART.
3. X-Ray Photography. EUGENE R. CORSON.
4. Some Facts of Responsibility in Spirit and Drug Takers. T. D. CROTHERS.

5. An Unusual Case of Partial Recovery from Embolism of the Arteria Centralis Retinae. EDGAR S. THOMSON.

1.—Max Einhorn discusses the condition of enteroptosis, which he believes may exist without giving rise to any symptoms whatever; but, on the other hand, that enteroptosis may be accompanied by all kinds of gastric and intestinal actions. The corset seems to be an important factor in the causation of these anomalies, but it certainly is not the only cause. Enteroptosis may be found in very young women, who have never worn a corset, and also in men. A weakened condition of the abdominal walls appears to be a primary and most important factor in its causation. Enteroptosis is accompanied in most instances by a movable kidney, and the latter can also be taken as an index for the occurrence of the former. McPhedran is authority for the statement that enteroptosis is not more frequent in women than in men, but in Einhorn's last 45 cases, 26 were in females and 19 in males. Looking over a large number of cases, Einhorn has found in 1912 patients suffering from visceral ptoses, 1080 males and 832 females. Most of the cases of enteroptosis, of which there were 240 in a series, were accompanied by a movable kidney, namely, 212; 18 in men and 194 in women. Enteroptosis may exist without giving rise to symptoms, but the patient often complains of a faint feeling or a certain weakness after rising. There is frequently considerable fatigue after slight exertion, especially after walking. In women, pronounced backache is often present. Flatulence, constipation and frequent micturition are commonly present, and these conditions do not yield readily to treatment. Cases of enteroptosis lasting a long period frequently lead to pronounced anemia in consequence of subnutrition. The latter gives rise to a host of manifestations (neurasthenia). Patients with enteroptosis are usually thin and slender, and often appear younger than they really are. The abdominal walls are generally flaccid, and palpitation is usually easily executed. The abnormal position of the stomach can easily be demonstrated by the following procedures: 1, the splashing sound; 2, inflation of the stomach with gas, and 3, gasto-diaphany. Strong pulsation of the abdominal aorta is frequently encountered, and is probably due to the partial uncovering of this organ by the slipping down of the stomach. The transverse colon, the cecum and part of the ascending colon, as well as the sigmoid flexure, can often be distinctly palpated. The transverse colon is frequently found in these cases as a ribbon-like body running horizontally above the navel. The diagnosis is easy. Einhorn calls attention to Glenard's "belt-test" as a valuable auxiliary in diagnosis. The physician stands behind the patient and encircles the lower part of the abdomen with both his hands; at the same time supporting and partly lifting the patient. If this procedure gives relief it favors the presence of enteroptosis. The prognosis is good when appropriate treatment is instituted. The principal treatment consists in the application of a well-fitting supporter, and in supplying with ample nutrition and well-regulated exercise. Excellent illustrations of several devices accompany the article. Electricity is especially adapted when administered intragastrically to cases in which there are manifold disturbances of the stomach. Iron and arsenic are frequently indicated, and the digestive disturbances managed according to the general rule. Too many laxatives, however, should not be given. [T. L. C.]

3.—Eugene R. Corson presents a practical paper, the results of his own wide experience in X-Ray photography. At first he uses a coil giving a thin 10-inch spark, but now employs one giving a very fat and multiplied spark of 10 inches. This change has produced a startling difference in his photographic results. The difference is due to the amount of current going through the tube. The time of exposure and the time necessary for developing are both shortened, and he secures a negative which brings out the parts more clearly and with more detail. For diagnostic purposes the fluorescent screen of potassium platino-cya-

nide is a most valuable addition to the X-Ray outfit, especially when a very thick part is to be examined. The salt gives a bluish light and acts with greater rapidity on the photographic plate. The time of exposure is greatly shortened, about one-fourth the time being necessary. With a screen made by Erneck's, of Berlin, the author could secure a good negative of the hip in 1 1-2 to 2 minutes. [T. L. C.]

4. T. D. Crothers contributes some facts upon the responsibility in spirit and drug takers. The writer wishes to make it prominent, not that there is legal irresponsibility in these cases, but that the present legal standard is wrong and contrary to all the teachings of science. The superstition that insists on full measure of accountability in all cases in which spirits are used, and assumes that the use of alcohol is the voluntary act of the brain, both conscious and capable of control, is a sad reflection on the intelligence of the present age. The interpretation of the law that boundary lines of responsibility and irresponsibility can be marked out in a case of inebriety, is a delusion. To-day a large percentage of all medico-legal cases is associated is decided from theories formulated centuries ago. The real responsibility and accountability is very different from the conception of them formed in courts of justice. Modern facts of science show clearly the influence of heredity, of injuries, of strains, of drains, of failures, of diet, of surroundings, of culture, of ignorance, and all the vast range of influences and forces which enter into the acts and character of every person. [T. L. C.]

5. Edgar S. Thomson reports an unusual case of partial recovery from embolism of the arteria centralis retinae, occurring in a man 59 years old. The descending artery was almost obliterated and the ascending one much reduced in size. Under correction fair vision remained. A restoration of the entire upper half of the field was obtained down to within 10 degrees of the macula. There was no light perception either at the macula or in the lower half of the field. No further loss of vision occurred, the patient dying one year after the embolism from heart disease. The relation of cilioretinal vessels to the retinal circulation is discussed. [M. R. D.]

MEDICAL NEWS.

March 30, 1901. (Vol. LXXVIII., No. 13.)

1. The Immediate and Remote Results in One Hundred Conservative Operations on the Ovaries and Tubes: with Brief reports of Four Cases. W. L. BURRAGE.
2. Tropocaine Hydrochlorate.—A Substitute for Cocaine Hydrochlorate in Spinal Anesthesia. WILLY MEYER.
3. A Study of Cases Presenting Symptoms of Asthenopia and Anomalies of the Ocular Muscles in which Ablation of the Middle Turbinal Was Effective Treatment. HEBER NELSON HOOPLE.
4. Acute Traumatic Malignancy. WILLIAM B. COLEY.
5. The Akouphone and Its Limitations. J. A. KENEFICK.

1.—Burrage, in his article on The immediate and remote results of operations on the ovaries and tubes, gives in his immediate results the following: Three patients died out of 156 operations. In the early operations there was marked enlargement of a resected ovary in the weeks immediately following operation; the enlargement disappeared in the course of time. Some of the patients had a good deal of pain. These last conditions—enlargement and pain—were markedly less in his recent cases, and he thinks were due to free puncturing of cysts without especially careful measures to produce hemostasis, and that the enlargements were caused by pain as well as by trauma. Pelvic inflammatory exudate about ovaries and tubes has been noted in a few cases following resection of a closed tube, these being generally in old gonorrheal cases. His rule in performing all multiple operations is to do nothing more than can be done in two hours. Under the remote results, the preservation of ovaries and tubal tissue is considered. In the few instances this has been done the symptoms of the artificially induced menopause have

seemed to be lessened. The possibility of pregnancy occurring in the Fallopian tubes or in the abdominal cavity where the uterus has been removed and ovary and tubes are left is to be considered. (T. M. T.)

4.—Will be abstracted when concluded.

5.—Kenefick describes the akouphone as a telephone whose electric force is supplied by a compact storage battery of six volts. The transmitter is fitted with one or a series of dome or funnel-shaped resonators for the purpose of gathering in and concentrating sound waves from all sources in its immediate neighborhood. This receiver is so conducted that all sounds conducted to it are reproduced or retransmitted with such force and intensity and penetration which is magnified still more on account of the closure of the external auditory meatus by the instrument which is held so that it completely covers it. The storage battery is concealed about the person. The intensity of the receiver action is adjusted either by manipulating the adjustment of the diaphragm or by means of a sliding switch on the handle. Persons seeking mechanical aid generally come under the following heading: (1) Those whose membrane and ossicles are intact, but functionally embarrassed by sclerosis or injury while the nerve is yet free. In these cases we find flaccidity of the tympanic membrane and hyperesthesia of the acoustic nerve. The tensor tympani has no function and fails to protect the hyperesthetic nerve terminals in the labyrinth against these new sound waves, therefore resorting to any mechanical aid under these circumstances would not be advised. (2) In these cases whose conducting apparatus is embarrassed by the absence of the ossicles or the greater part of the tympanic membrane, the nerve remaining free, it would seem theoretically favorable for the akouphone on account of the protection afforded the nerve terminals by the intervening bone. (3) Those in whom there has been disease involving, but not wholly destroying the labyrinthine nerve terminal—deaf mutes. In these cases we find the greatest field for the practical use of the apparatus in teaching these unfortunates articulate speech. (4) Those whose deafness is caused by destruction of the nerve function somewhere in its central course do not receive any aid from the akouphone. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

1. A Review of the Literature of the Therapeutic Use of the X-Rays. HARVEY P. TOWLE.
2. Pathology of the New-Born as Illustrated in the Practice of the Writer. FREDERICK W. TAYLOR.
3. Oblique Subtrochanteric Osteotomy, for the Lengthening of the Femur, and Correction of the Deformity of Flexion Resulting from Hip Joint Disease. E. G. ABBOTT.

1. After a review of the literature of the therapeutic use of the X-rays, Towle concludes: (1) That the real nature of the X-rays is not yet determined definitely, nor whether the therapeutic result of their use is due to the action of the rays themselves or of something of electrical origin accompanying them; (2) that the treatment is not without danger, unless the greatest care is used; (3) that the effects of the X-rays run a slow course; (4) that whatever may be the exact origin of the effects produced, a definite reaction is induced in the skin by the use of the X-rays; (5) that the changes induced in the skin are similar histologically to those seen in ordinary inflammation; (6) that the X-rays are not proved to have any bactericidal power; (7) that their therapeutic effect is probably due to the inflammation excited; (8) that hair can be removed by their use, and that lupus and several other diseases can be healed over; (9) that in a few reported cases we may fairly assume that a permanent cure has been effected, but that in a majority of the reported cases too little time has elapsed to rule out the possibility of a return of the disease; (10) that the effect of exposure to the X-rays is so extraordinarily slow in disappearing that months should elapse before an absolute cure is assumed; (11) that while the permanency of the cure effected may perhaps be doubtful as yet, it is certainly desirable to experiment further. [J. M. S.]

2.—Out of 654 cases of labor, 64, or nearly 10% of the children were abnormal either at birth or during the first few days of life. Of the 23 stillborn infants, 9 were delivered by forceps. In 8 of these cases the forceps were applied high. The number of children born alive but dying within a few days of birth was 22, 3 of which were delivered by forceps, applied high in two cases and low in one. On one case the child cried normally immediately after birth, but within 2 or 3 minutes the breathing became obstructed. This was followed by a discharge of perhaps 2 drachms of yellow, frothy mucus from the nose while the head was dependent. Respiration then returned and was clear for a time. An attempt to feed the child was followed by an attack of dyspnea and discharge of liquid through the nose. A bougie passed through the nose met an obstruction 5 inches from the nostril. The child lived less than 2 days. At autopsy, a short distance below the level of the cricoid cartilage the trachea and esophagus were firmly joined by connective tissue. The upper part of the esophagus was a blind pouch. The lower part of the esophagus communicated at its upper end with the trachea by an opening about a line in diameter. Above this opening, on the posterior wall of the trachea, there was a shallow groove. In a case of meningocele, the temperature rose to 107° F. on the second day, and death occurred on the third. The tumor contained cerebrospinal fluid and brain tissue. The cerebral hemispheres were small, and the corpus callosum absent. In 10 cases, there was delay in respiration. In 6 of these cases the children were delivered by forceps; in the other 2, delivery was by podalic version. Frederick W. Taylor also records one case of hare lip and cleft palate, one of vascular nevus, 3 of ophthalmia, and 2 of melena. One child was born with a depression in the left frontal bone, which, within 4 weeks, had returned nearly to its normal contour. Another child had left facial paralysis, which had so diminished by the eleventh day as to be hardly perceptible. Forceps had been applied in the case when the head was well in the pelvis, with occiput R. A. [J. M. S.]

3.—E. G. Abbott reports the details of a method of performing oblique subtrochanteric osteotomy for lengthening the femur and describes an illustrative case. [J. M. S.]

2.—Sam. Lloyd thinks that certain cases of Pott's disease with paraplegia may be benefited by a laminectomy. Where there has been complete degeneration of the cord, of course, no operation could be of benefit, nor is it applicable when there are tubercular lesions elsewhere in the body or where there is general and advanced sepsis. The cases most benefited by the operation are those in which the disease is distinctly in the posterior portion of the

spine. The operation should only be done where other methods have been tried and have failed. Lloyd has performed 15 operations since '92. None of the patients have died from the operation, and 2 have been successful. Operations in the cervical region are much less satisfactory than those in the dorsal and lumbar. A collection of 154 cases has been made, and Lloyd's conclusions are drawn from a study of these cases. Two deaths have followed hemorrhage from the vertebral artery in operations on the cervical vertebrae. He concludes that the operation is seldom successful and seldom indicated, but that undoubtedly certain cases call for the operation and are benefited by it. [J. H. G.]

3.—DeForest Willard urges upon the general practitioner the great necessity of the early recognition of tubercular lesions of the joints, maintaining that many cases which go on to suppuration and ankylosis might be aborted if a diagnosis were made early and treatment promptly instituted. He calls attention to the great mistake of supposing that joint pains in children are due to rheumatism. Another prevalent error is that only the children of tubercular parents are liable to develop tuberculous lesions of the joints. In making a diagnosis in the early stages, the most significant symptom, and the one which should make the physician suspicious and cause him to put the part absolutely at rest, is muscular rigidity. Pain and tenderness may be entirely absent in these cases in the beginning, and therefore are not at all necessary to a proper diagnosis. The local symptoms of inflammation are also absent in the early stages of this condition. [J. H. G.]

4.—J. Rilus Eastman has in a number of cases used prolonged permanent catheterization without developing any of the evil effects which are supposed to follow this form of treatment. He has found it particularly useful in cases of resection of the urethra, where an anastomosis is made. The best results are obtained from the use of a large catheter, which is only allowed to pass a short distance into the bladder. Occasionally there is some secretion around the catheter from the mucous membrane, but with occasional irrigation, with a solution of permanganate of potash, this promptly disappears. In a number of cases of perineal section, he has been able to keep the catheter in the bladder until the wound is entirely healed. [J. H. G.]

5.—John B. Roberts thinks that many cases of syphilitic deformity of the nose are advised to have nothing done, when in fact a plastic operation would largely do away with the disfigurement. He urges that the patient should be made to understand that one operation, or even two, may not result in complete success, but that it is sometimes necessary to do a number of operations, and that the time required will be from six months to a year. Roberts thinks that most surgeons will operate for deformities involving the soft parts of the nose, but that when the bony bridge is affected, oftentimes operation is not undertaken. [J. H. G.]

6.—Shattuck discusses the medical treatment of peptic ulcer. From a standpoint of diagnosis, he recognizes three varieties of gastric ulcer: (1) The latent forms without symptoms until the appearance of hemorrhage or perforation. (2) Those characterized by dyspeptic symptoms. (3) Those with symptoms which are diagnostic. He recommends absolute rest for two weeks, during which time rectal feeding should be enforced rigidly. In some instances the period of rest is continued longer than two weeks, while in a few the time is shortened. Stomach unrest and vomiting has been provoked in a few cases by the rectal injection. The sense of hunger subsides as soon as the stomach ceases to work, and if hunger persists, small doses of morphia are recommended. The nutrient enemata are given every six hours and a cleansing enema daily. Small quantities of water are allowed by the mouth, and in some cases water is introduced into the rectum, or under the skin, to quench the thirst. At the present time, judging from the statistics, the author recommends prolonged rest of the stomach. [F. J. K.]

7.—Spivak, in an article on lavage of the stomach as a

therapeutic agent in the treatment of habitual constipation, comes to the following conclusions: (1) In some individuals suffering from habitual constipation, spontaneous bowel movements follow the first lavage of the stomach. (2) Recovery occurs in the majority of patients if lavage be continued for a period of two or three weeks. (3) The use of cold water, or hot and cold water alternately, gives promise of the best results. (4) One hour before breakfast is the most favorable time for lavage. [F. J. K.]

8.—Dohme emphasizes the value of drug standardization to the physician. By uniformity in the strength of the drug, the element of doubt is removed from the physician's mind, the pharmacist avoids embarrassment, and the patient is sure of getting what is prescribed, therefore being advantageous to all parties concerned. [F. J. K.]

9.—Will be treated editorially. [F. J. K.]

10.—Bannister discussed the danger of contracting tuberculosis; whether the liability to contract the disease depends so much upon direct infection or upon constitutional and hereditary predisposition. Short histories of a number of cases are given, and the author suggests the following conclusion: that a much greater personal risk exists when the parent is phthisical, than from having a husband or wife who is tuberculosis. [F. J. K.]

11.—W. M. Cole discusses the pathology of keloid and calls attention to the fact that the disease is not confined to the skin alone, but is also sometimes met with in the mucous membrane. For instance, on the conjunctiva and on the tongue. He reports a number of cases where he has had very satisfactory results from complete excision of the growth with careful coaptation of the skin wound. Where the skin edges cannot be brought together skin grafting will often result in success. [J. H. G.]

12.—Class in an article on immunity against zymotic diseases believes that in districts where certain zymotic diseases are endemic, there is a wide distribution of the germs of the disease in question, and that the microorganisms are present in an attenuated form. When the germs become virulent they are apt to produce an epidemic. The infection by attenuated germs renders an individual immune or insusceptible against a given zymotic disease. [F. J. K.]

13.—Will be treated editorially. [F. J. K.]

1.—William Osler presents a paper on the medical aspects of carcinoma of the breast, with a note on spontaneous disappearance of secondary growths. Osler mentions that a large majority of patients with this condition suffer from internal metastases after operation. In one case which he saw with Dr. Agnew eighteen years had elapsed since the discovery of the breast tumor. On the other hand these growths may appear with extraordinary rapidity. The cases may be arranged into those with cerebrospinal thoracic and abdominal manifestations. The tendency of secondary carcinoma to involve the bones, especially those of the spine, makes the complication of this group very frequent. Secondary cancer of the bones of the

skull is very infrequent, as is secondary cancer of the brain. Osler reports one case with symptoms of brain tumor occurring 18 years after the appearance of scirrhus carcinoma of the breast. Dr. Agnew had seen the case in its incipency but had advised against operation, and the growth had gradually become shrunken. The spinal manifestations are perhaps the most important of all the groups. The main characteristics of this involvement are pains of great intensity, usually about the sides and down the legs, or if the secondary masses are situated higher, they may be in the arms. Alterations of sensation are common. The crisis of pain are frequently unbearable. Osler records 7 cases with this complication which are the most notable which he has observed within the past 8 years. The clinical notes are included in the article. The thoracic manifestations from the proximity to the original disease are extremely common. There are three groups of such cases; the pleural, glandular and pulmonary. Of the pleural variety, Osler reports two cases. In general there are pains in the chest, sometimes with signs of an acute pleurisy; there is a gradual effusion and the case may be first seen with all signs of a large exudate. The effusion may be the result of acancerous pleurisy, or it may come from pressure of enlarged mediastinal glands on the azygos and other veins. There are many cases of hydrothorax referred to in the literature. By far the most distressing features of breast cancer are seen in the cases in which the bronchial and mediastinal glands are involved and in which the patient dies from gradual suffocation. Osler reports one case of this variety recently seen and recalls the death of two patients within a few years from this condition. Secondary scirrhus of the lungs is not very common, except the presence of scattered nodules seen postmortem. Encephaloid is more frequent. The abdominal manifestations may be divided into two groups, the peritoneal and hepatic. These secondary growths may invade the omentum and peritoneum, with nodular masses in the mesenteric glands with, or without ascites. In a case which Osler details the masses appeared to be in the omentum and peritoneum. Cancer of the liver secondary to cancer of the breast is very common. Osler gives short histories of 2 illustrated cases. In conclusion Osler discusses the spontaneous disappearance of secondary growths, illustrating the fact that no condition, however desperate, is quite hopeless. In two of the cases of Dr. Osler's theories spontaneous disappearance of the secondary growths took place. The spontaneous involution seen occasionally in the primary growths of the breast affords an explanation of the disappearance of the symptoms in some cases with secondary metastases. The treatment is most unsatisfactory. Morphine alone gives relief. [T. L. C.]

2.—A. H. Cordier discusses the operation of gastrojejunostomy in gastrectasis. Two illustrative cases are presented. Cordier states that cancer of the pylorus even though removed returns quickly and always kills. Pylorotomy is attended by a high mortality and is not justified in advanced carcinoma of the pylorus. The operation as advised by Wolfier and Von Hacker that of gastrojejunostomy best meets the indications. It is not necessary to twist the bowel in making the anastomosis to prevent bile from entering the stomach. The anastomotic opening in the stomach should be at the most dependent point of the dilated organ. The operation is attended with a low mortality. Tables are appended. The author believes that in all cases in which marked dilation of the stomach exists, accompanied by emaciation, pain and an invalid state, this operation should be performed. The patient gains rapidly in weight, and if the disease is non-malignant, good health is restored. [T. L. C.]

3.—John B. Deever presents a paper upon the mortality of operations for obstructive jaundice. A careful study of the causes of the mortality of this condition leads us to the consideration of the best methods of combating the disease. The most common of all causes is obstruction from gall stone. Parasites are so rare that they may be passed with the mention, although the indication is distinctly surgical when they do occur. The most common cause of death is hemorrhage caused by changes in the blood. The next most common is exhaustion, or what we believe to be cholemia. The third most common is shock, which is the result of hemorrhage. Deever believes that early operation offers the best safeguard to the destructive possibilities of obstructive jaundice due to cholelithiasis. Strictures, or obliteration of the duct, tumors, closing the

orifice of the duct, or growing into its interior, pressure from without by tumors of contiguous organs or by enlarged glands, in fissure of the liver, present unmistakable surgical indications. Marked jaundice, especially of long duration, offers serious obstacles to operative interference. Yet in some cases the risk must be assumed. Deaver classes these cases as the "fulminating type" of the disease. A differential diagnosis is often difficult to establish, but Deaver points out that general peritonitis which is a usual accompaniment of fulminating appendicitis is unusual in disease of the biliary apparatus. In either case operation should be synchronous with the establishment of a diagnosis. Operation is advisable even if this cannot be absolutely determined. Deaver includes the report of 5 cases in this paper. [T. L. C.]

4.—A. M. Phelps reports 1650 operations for club-foot by his method. In 1878 he performed his first operation of open incision, upon a relapsed club-foot. Since that date he has operated upon 1650 cases. In his first series of 538 cases he performed 17 osteotomies. In the last 1100 he has never resorted to osteotomy, but has amputated 4 times. Over 100 of his cases occurred in adults varying in age from 20 to 60 years. The operation of cuneiform resection by Davy, of London, and that of resection of the astragalus by Lund marked another period in operative treatment. There is no mortality in Phelps' operation. Any foot at any age can be straightened, and the results from the operation are equal to that from any bone operation, or mechanical treatment. The method by which Phelps proposes to govern the management of club foot requiring operative work is given. The paper is profusely illustrated. Phelps' observations have led him to the following conclusions, among others given: All feet at any age after the fourth month, with shortened skin and ligaments, should be operated upon by open incision. Prolonged medical treatment is unjustified. Club-foot shoes of every name and nature have been discarded, and manipulation by the hand is advised. A case cannot be said to be cured, and free from the dangers of relapse, until the heel strikes the ground first in walking. A cure is effected when new facets are formed on the tarsal bones. [T. L. C.]

5.—H. A. Hare reports an obscure case of hysteria with associated right mydriasis and amblyopia and left myosis. The patient was a woman of 33 years who suffered from scarlet fever at 15 years, from which she did not recover for two months. She went out into the snow with the eruption still upon the body. During that time she had much pain on the right side and lower axillary region and in the lumbar region. These attacks have occurred at irregular intervals ever since, usually about 2 weeks apart. After these paroxysms small white stones about the size of a grain of buckwheat have been found in the stools. On one occasion a stone the size of a cherry was found. For five days preceding this discovery the patient was unable to move arms, legs or body, and her vision and hearing were imperfect although she was not in great pain. Eleven years ago while writing she found her sight deficient and discovered that one eye was entirely blind. For the past 4 years the left pupil has been tightly contracted but the vision was good. The right pupil was widely dilated. After the period of 5 years referred to she was comparatively well for 2 years when she fell violently, injuring the waist region. Following the fall there was a discharge of pus and blood from the rectum. Operation was performed but no pus or stone was found. Dr. de Schweinitz diagnosed the case as one of hysteric amblyopia. When the patient was fitted with proper glasses, vision markedly improved, and under proper treatment, including massage and Swedish movements, the symptoms almost entirely disappeared. [T. L. C.]

WIENER KLINISCHE WOCHENSCHRIFT.

1. The Primitive Organs of Sight. T. BEER.
2. Ligation of the Jugular Vein in Thrombosis of the Lateral Sinus. F. ALT.
3. Sutures in the Heart. H. ZULEHNER.

1.—Will be abstracted when completed.

2.—After a detailed review of the literature of his subject, Alt reports two cases of thrombosis of the lateral sinus following chronic suppurative otitis media. In both cases Alt laid open the sinus, removing the clots. In one case,

the jugular vein was ligated. Infection of the thrombus contained in the ligated vein followed; it was opened, cleaned out, and again ligated. Both cases recovered eventually. From the literature quoted, it seems that those cases, in which it is not considered necessary to ligate the jugular vein, have a slightly better prognosis than those in which ligation must be done. [M. O.]

3.—Zulehner reports the case of a man of 35, who was stabbed in the chest and abdomen. The upper wound penetrated the heart. This was opened and an attempt made to suture the wound, (only half a cm. long,) in the wall of the left ventricle. The fine sutures tore out at once, and the patient bled to death on the operating table. The heart showed marked fatty degeneration, was hypertrophied, and its walls were very brittle. All the viscera were anemic. The abdominal wound had supplicated, producing peritonitis. Out of 10 cases so far known in literature, only three recovered. Zulehner quotes the first of the three, a man of 22, who had been stabbed. I wound over 1 cm. long in the right ventricle was sutured with catgut. Zulehner's experience shows how hard a task it is to attempt to suture the heart muscle. [M. O.]

JOURNAL DE CHIRURGIE.

1. Suppurative Arthritis of the Knee. LAUWERS.
2. Intestinal Resection for a Diffuse Neoplasm of the Pelvis. KEIFFER.
3. A Rare Case of Teratology. LORTHIOIR.
4. Spontaneous Rupture of an Umbilical Hernia. DANDOIS.
5. A Case of Pneumococcic Peritonitis. VANDERLINDEN.

1.—Lauwers reports two cases of purulent arthritis of the knee, in adults, due to staphylococci. One followed purulent conjunctivitis, the other was puerperal. The first case recovered with simple drainage and fixation. In the second case, the femur was so diseased that Lauwers amputated at the lower third of the thigh. She recovered quickly. [M. O.]

2.—Keiffer reports an intestinal tumor occurring in a woman of 30. Two years ago, the tumor filled the entire pelvis. The urine was normal, as was menstruation. He performed an exploratory laparotomy, and found a diffuse tumor, covering the bladder, uterus, adnexa, small intestine, and descending colon. While trying to find the origin of the tumor, part broke off in the hand of the operator. This showed the large intestine passing through it. As the rectal end of the broken sigmoid flexure could not be found, Keiffer made an artificial hypogastric anus. During the two years since the operation, the patient has been in good condition, the abdominal viscera have become free and are now palpable, and the tumor has been absorbed, following functional disuse of the lower end of the large intestine. Exploration of the rectum shows that this has closed. The part of the tumor removed shows fatty and subperitoneal connective tissue in great quantity, compressing the intestinal walls, about which it had grown. [M. O.]

3.—Lorthioir exhibits the photograph of a man of 18, with a third leg, short and misshapen, formed by two rudimentary legs, having a long foot with ten toes. He had a penis on each side of the median raphe, with a distinct, separate scrotum, each containing one testicle. Urine and spermatic fluid passed from each penis simultaneously. It is not known how long this Portuguese specimen of congenital malformation lived. [M. O.]

4.—Dandois reports a case of umbilical hernia in a woman 58 years of age, which had existed 15 years. The hernia ruptured suddenly, and Dandois, four hours later, performed a successful operation for its radical cure. [M. O.]

5.—Vanderlinden reports a case of peritonitis, occurring in a woman aged 29 years. She had borne five children, the last one but a few months before. Peritonitis came on suddenly, two weeks before, with vomiting, diarrhea, and metrorrhagia. Laparotomy was performed, the pus cleaned from the peritoneum, and drainage instituted. The pus contained typical pneumococci. Double bronchopneumonia, and death followed. The autopsy showed an intestinal perforation, which probably was the cause of death. A full review of the literature of pneumococcic peritonitis follows. [M. O.]

THE LOCALIZATION OF BRAIN TUMORS ESPECIALLY
WITH REFERENCE TO THE PARIETAL AND
PREFRONTAL REGIONS.*

By CHARLES K. MILLS, M. D.

Professor of Mental Diseases and of Medical Jurisprudence in the University of Pennsylvania; Neurologist to the Philadelphia Hospital.

During a little more than a year past I have examined and given opinion as to the site of lesion in five cases of brain tumor, and in a sixth case which proved to be one of softening and degeneration, but in which the diagnosis of tumor was considered probable. Two of these cases occurred in my own practice, in one case I was called in consultation by Drs. S. Weir Mitchell and J. K. Mitchell, in two others by Dr. W. W. Keen, and in the last by Dr. W. Sinkler. All of these cases were operated upon by Dr. Keen, and one by Dr. W. J. Taylor. The operation in each case revealed the lesion in the location previously indicated. In four of the cases of unequivocal brain tumor the growth was removed in whole or in part; in one it could not be removed owing to the condition of the patient; and in the sixth case a portion of the diseased tissue was removed. I shall confine my remarks to a brief presentation of the cases, and to a few salient points regarding localization. Four of the five cases, as nearly as could be determined, began in the parietal region and were largely confined to it; a fifth was prefrontal in origin and location, and a sixth was mainly in the motor zone.

CASE I.—*Tumor of the Superior parietal Convolution (Parietal Convolution of Wilder); Localizing Symptoms—Impairment of Cutaneous Sensibility, Loss of Muscular Sense, Astereognosis, Ataxia, Paresis and Ultimately Paralysis; Operation, Recovery.* **The patient was a man 57 years old who had suffered from nervous symptoms for a number of years. The data which led both to the general diagnosis and to the localization of the growth were summarized in the paper read before the American Neurological Association as follows: About five months previous to the operation the patient began to show some ataxia in the right arm and later in the right leg, and when investigation of his condition was first made by the writer all forms of cutaneous sensibility were impaired, muscular sense was lost, and astereognosis was a marked symptom. As the case progressed paresis and eventually paralysis of the arm and leg supervened, this when complete of course masking the ataxia. The patient developed a disorder of speech chiefly showing itself as a verbal amnesia and fatigue on reading. At one examination the patient showed a temporary partial right hemianopsia. Reversals of the color fields and contractions of the fields for form similar to those supposed to be typical of hysteria were present at several of the examinations. The reflexes on the ataxic and paralyzed side were somewhat exaggerated, ankle clonus being present. The patient was emotional and markedly hysterical. The general symptoms of brain tumor were not prominent, but the most important of them were absent.

It will be seen from this summary that the localization of the lesion in the parietal region was decided upon chiefly by a study of the sensory symptoms present. Almost all the sensory ele-

ments which go to make up the stereognostic sense were more or less impaired in the comparatively early history of the localizing phenomena of the case. True motor paralysis was at this stage absent, although it not only ensued, but became a prominent and masking feature of the case as time progressed, and as the tumor encroached more and more upon the motor region. The paresis was at first undoubtedly a pressure manifestation; later the Rolandic subcortex, and, to some extent, even the cortex, became implicated in the morbid growth.

I shall not dwell further on this case, which has already been fully reported, except to recall that the operation by Dr. W. W. Keen, which was in the highest degree successful, was conducted with the view of uncovering the superior parietal convolution as the central point of the procedure; and also to say that now, after the lapse of fourteen months, the patient remains in good general health, in about the same condition as he was at the time when the last report on his case was made, except that he has still further improved as regards the use of his upper extremity. No signs of the return of the growth have been observed.

Case II.—*Tumor of the Superior Parietal and Middle Portions of the Central Convolutions; Localizing Symptoms—Impaired Cutaneous Sensibility, Loss of Muscular Sense, Astereognosis, Ataxia and Late Paralysis; Operation, Death; Autopsy Showing the Site of the Lesion as Above Indicated.*

*The patient, a man 65 years old, five weeks before the operation, noticed gradual loss of power in the right hand, with impairment and changes in sensation. The notes stated that he would drop things from his hand unconsciously; that he could not tell that he held things in his hand except by looking; and that he did not know whether or not his fingers were in his pocket. It has seemed to me not improbable that the apparent paresis spoken of may at first have been a loss of control or co-ordination. Not infrequently the awkwardness and ataxia in the use of a member which come on as the result of impairment of the cutaneous, muscular and stereognostic sense are regarded by the patient and others as a true loss of power. This was true of Case I. and Case IV. of this series. Uncertainty in the use of the right leg came on within a week or ten days. The patient said that he felt as if a cushion was under his right foot. Nearly three weeks before the operation, that is, two weeks after the onset of the active symptoms above noted, examination showed that pressure sense was absent all over the hand; that the pain and temperature sense were also absent in the right upper extremity, most markedly in the ulnar distribution in the hand and forearm, on the ulnar side of the arm, and also in a small region just in front of the shoulder joint; that muscle sense and power were diminished, although the latter was still considerable; that the Babinski reflex could be obtained in the great toe, and the right arm jerks were absent. Other reflexes were presumably normal, as they were not mentioned. Ten days before operation the man suffered with severe cephalalgia, chiefly in the left temporal region, great throbbing of the left temporal artery

on that side being visible. November eleventh six days before the operation, the patient had a severe attack of tonic spasm in the right arm, which lasted fifteen minutes. About this period ophthalmoscopic examination showed marked left optic neuritis and beginning neuritis in the right eye. No hemianopsia was present. At a spot near the coronal suture, half way to the vertex, there was tenderness to pressure. From November eleventh the patient's right arm and leg grew steadily weaker, and his headache steadily worse. The patient was first seen by Dr. Keen November 17th, who confirmed the observations of Dr. Nichols as

*Read at the meeting of the Philadelphia Neurological Society, January 28, 1901.

**This case has already been published in detail in a paper which was read before the American Neurological Association at its Washington meeting, May, 1900. *Journal of Nervous and Mental Disease*, v. 27, No. 5, May, 1900.

*This man was a patient of Dr. Charles I. Nichols, Worcester, Mass. He was operated on by Dr. W. W. Keen November 17, 1900. A few months after the operation Dr. Keen consulted me in Philadelphia, and the site of the tumor leading to me at this time a letter of Dr. Nichols in which the most important in the history and symptomatology of the case were clearly presented, etc. Keen and I agreed as to the location of the growth.

given in the preceding notes. In my consultation with Dr. Keen I suggested that the location of the tumor was probably about the same as that in case I., namely: that it was mainly in the superior parietal convolution with some invasion of the motor region, this being also in accord with the views held by Dr. Keen. An osteoplastic operation was performed November 17, 1900, and I am indebted to Dr. Keen for notes of the operation, from which I have condensed the points essential to my purposes in this paper. The opening was made 10 cm. along the middle line, 12 mm. to the left of it, and was so placed that its anterior border should uncover the upper portion of the central fissure. The two vertical incisions were each 7 cm. long. On opening the dura the brain bulged in a few minutes up to above the level of the scalp. At the anterior portion of the opening was seen the oblique central fissure. Precisely at the centre of the opening in the skull was an area of discoloration about 15 mm. in diameter, evidently the result of a subcortical growth just bursting through the cortex. A large tumor was as far as possible enucleated. Some portions not reached by the first enucleation by the finger were curetted. The patient stood the operation well. Chloroform was administered by Dr. Nichols, and Dr. Keen was assisted by Drs. Homer Gage and Fisher. At 4.30 on the afternoon of the day of the operation the patient was perfectly conscious, temperature normal, pulse 114, and neither speech nor face was in any way affected. He grasped the hand of the doctor with his right hand, which he moved as well as before the operation. At 10 P. M. on the same day about the same conditions obtained, but he had a restless night, developing much pain in the head. The next morning the temperature had risen to 101 degrees, and his right arm and leg were totally paralyzed. Late in the afternoon of November 18th his condition had not changed much for the worse, but he soon after began to fail, and died November 19th.

An autopsy was made by Dr. E. H. Baker, the city bacteriologist of Worcester, twenty hours after death. The account of the autopsy indicated that a large oval cavity was left which was filled with blood and debris. The cavity seemed to have included the superior parietal and middle portions of the central convolutions and adjoining subcortex, although the first is not mentioned. The superior parietal convolution, from Dr. Keen's description of the operation, must have been in large part removed. The growth was single, and not encapsuled. Later a microscopical examination by Dr. Baker showed it to be a gliosarcoma.

I shall not make any detailed observations on sensory phenomena in conjunction with the study of this case, simply saying that the remarks on this subject, in connection with cases I., III. and IV. are equally applicable here. The diagnosis of a lesion, in large part posteroparietal, was based chiefly on the presence of sensory phenomena.

It will be noted that six days before operation the patient had a severe attack of tonic spasm in the right arm, which lasted fifteen minutes. This symptom is of interest as probably indicative of invasion or irritation of that portion of the motor subcortex which is related to the arm centre. It was long since pointed out by Seguin and the writer that paresis, with predominance of tonic spasm, pointed to a subcortical lesion in the motor zone. Recently, in a case dying in the Nervous Wards of the Philadelphia Hospital, a tumor located in the motor subcortex and limited to this region, was found. The patient was partially hemiplegic, and had a persisting spastic condition in the upper extremity of the paralyzed side.

CASE III. Tumor of the Superior Parietal Convolution; Localizing Symptoms—Impairment of Muscular Sense, Astereognosis, Ataxia, Paresis; Operation Recovery. This patient a bright boy 8 years old, was brought to Dr. Keen for operation by Dr. Daniel Z. Dunott, of Baltimore, Maryland. I had been furnished by Dr. Keen and Dr. Dunott with notes of the history of the case before it was seen by me.*

*Dr. Dunott expects eventually to publish an account of this case in detail.

I examined the patient on January 10th and 12th, 1901. The operation was performed January 14th, 1901. About one year previous to the operation a great change in the boy's disposition was noted. In June, 1900, he began to have headaches, which returned at intervals and soon were accompanied by vomiting. In October, 1900, he had an attack of paresis in the left leg and arm, more marked in the former, the attack passing off in a few hours. Dr. Dunott regarded the case as probably one of brain tumor. The patient was seen October 8th, 1900, and also December 16th, 1900, by Dr. William Osier. At this time he showed marked paresis of the left leg, particularly in the peroneal group, and also choked discs, but no disturbance or sensation or of the stereognostic sense was determined. Dr. Osier then confirmed the earlier diagnosis of Dr. Dunott of brain tumor, and advised operation. On examination Dr. Keen was struck with the fact that both on the right and the left side from the forehead back to the auricular line, tapping produced a distinct cracked-pot sound, perceptible not only to the ear, but to the other hand placed on the vibrating bone. He referred the patient to the writer and to Dr. G. E. deSchweinitz for examination from the neurological and ophthalmological points of view.

As I made a written report of my examinations and opinion to Dr. Keen, and as this report covers with sufficient fulness my observations of the case, I shall quote it here:

"The patient was distinctly paretic in the left lower extremity, the loss of power showing itself most in the extensors and abductors of the foot (chiefly in the peroneal group of muscles). The other leg and thigh muscles largely retained their power. He could stand and walk. Besides the paresis some ataxia of the left lower extremity was present, as shown in testing him by kicking at objects. Slight paresis, chiefly distal, of the left upper extremity was also present. The deep reflexes were all exaggerated on the affected (left) side. Ankle clonus was present at one examination and absent at the other. The Babinski reflex was especially noted at the second examination. Examination for touch, pain and temperature showed no loss, or so slight that it could not be measured. Careful and repeated examinations however showed a moderate degree of astereognosis as determined by manipulations of objects by the left hand. Although he sometimes recognized objects with the left hand, he always did this more promptly with the right, and in some instances he failed entirely with the left, although succeeding at once with the right. He could not promptly locate sensations in the distal portion of the left upper extremity, and sometimes failed entirely. When the little finger was touched or held, for example, he referred the sensation to the thumb or to another finger; when the finger or palm of the hand was touched, he referred the sensation to the wrist. In exceptional cases the localization was correct, but in three-fourths of the trials it was incorrect. He could properly designate any position in which the left lower extremity was placed, and the same was nearly true for the left upper extremity, but sometimes he did not seem to be quite sure of the posture in the latter case. Comparisons were constantly made with the right half of the body in arriving at these determinations. The left upper extremity showed some ataxia as well as paresis in testing by having the patient bring his fingers together, touching the nose, etc. Facial paresis and speech disorder were absent. Paradocontractility in the affected limbs was preserved. The patient could concentrate his attention readily, was prompt in his apperceptions, was keenly alive to all that was going on, showing unusual intelligence as regarded his examination, but he showed irritability and emotionality such as might be expected in a boy suffering from brain tumor or localized meningitis. A cracked-pot sound was elicited by percussing the skull on both sides of the median line in the frontoparietal regions. As reported by Dr. George E. deSchweinitz, at whose examination I was present, hemianopsia and all disorders of the ocular muscles, external and internal, were absent. Double optic neuritis was present. I have not thought it necessary to repeat the facts obtained by inquiry, all of which were contained in the history submitted to me before making the examination. The case is probably one of brain tumor, although the possibility of localized convexitv tubercular meningitis is worthy of consideration, and in either case operation in the same region is indicated. The lesion is probably

parietal, gradually encroaching upon the motor region. Hydrocephalus may be present."

An osteoplastic operation was performed by Dr. Keen, January 14, 1901. It is not necessary to give details of the operation; it will be sufficient here to record that, strange to say, a tumor, which proved to be a sarcoma, was found, with practically the same location and extensions as in the two preceding cases. The growth was removed by Dr. Keen, the patient recovered from the operation, and is almost in his normal health at the time of this report (March, 1901).

In this case, as in the two preceding, so far as could be determined by measurements and operative procedure, and in the second case by autopsy, the growth had begun in the subcortex of the superior parietal convolution. In each of these cases the tumor had advanced both toward the surface of the brain, and forward toward or into the Rolandic region. In the three cases my conviction as to the situation of the tumors was reached chiefly by a consideration of the disorders of sensation and co-ordination, which were present in all. In two of the cases cutaneous sensibility was more or less impaired, greatly in the first two and less markedly, but still certainly, in the last, at least at the time of my examinations. The previous examiners had not noted any astereognosis or impairment of sensation. In a cerebral case, when examination shows impairment or loss of cutaneous and muscular sensibility with astereognosis, I believe that we can with certainty look for the lesion, or that portion of it which causes these symptoms, in that part of the brain which lies between the post-central and occipital convolutions, and especially in the superior parietal convolution. These cases afford further confirmation of the views long defended by me in the face of much opposition, namely, that the sensory and motor areas of the cerebrum are, for practical purposes, distinct. Paresis and paralysis of a decided character were late symptoms.

In the third case, even at the time of my examination, impairment of sensibility, astereognosis and ataxia, were not of as marked a character as might be expected from a lesion of the dimensions of the tumor removed by Dr. Keen. It will be recollected that this tumor was of the right cerebral hemisphere, and one point to which I desire to call special attention in this contribution, is the probability that the recognition of various forms of sensation and the stereognostic sense may not be as highly developed in the right hemisphere as in the left, although their centres of representation are present in both hemispheres in the same locations. Just as the left half of the brain is the leading half for such highly evolved and differentiated faculties as speech, writing, right-handedness, word hearing and word seeing, so it is probable that the stereognostic sense and the elements which enter into it have their higher evolution in the left hemisphere. If this be the case, a lesion of the right hemisphere might not give symptoms referable to these senses of so decided a character as lesions of the left hemisphere.

In case III. it was a question before operation whether a tumor originating in the prefrontal lobe was growing backward and was thus invading the

motor region, or whether originating in the superior parietal convolution it was advancing forward into the motor region. As indicated in the report made by me to Dr. Keen, my view favored a parietal lesion advancing forward, this diagnosis being first, as just stated, based on the presence of sensory disorders and ataxia. The mental symptoms which undoubtedly were and had been present, were not in my judgment, such as belong to destructive lesions of the prefrontal regions. It was stated, and was undoubtedly true, that the boy's disposition had changed. It appeared to me, however, that the mental symptoms from which he was suffering were chiefly those of irritation and exhaustion, such as might have been expected from a tumor of considerable size, situated in almost any portion of the brain. On studying him carefully, I could not discover any real mental degradation, the boy being even a day or two before the operation unusually intelligent, concentrative and keen in his mental processes. Psychological symptoms of a definite character are usually present in lesions and especially destructive lesions of the region anterior to the motor zone. "Investigators have found more or less mental degradation to be the result of ablation or partial ablation of these (prefrontal) lobes, the animals losing the faculty of close attention and intelligent observation; and undoubtedly impairment and disturbance of a peculiar character occur both in the lower animals and in man from lesions of this portion of the brain. The higher and more complicated mental processes—those which involve such faculties as attention, judgment, and comparison—are always affected. Inhibition is impaired. Destruction of these lobes causes disintegration of the personality and incapacity to form serially groups of images or representations, more or less psychological dissolution occurring according to the extent of the lesion. Hesitation, uncertainty, fear, lack of force, weakness of the highest faculties, and motor, disquietude, due to loss of control, may be present."*

The mental change in the case under discussion showed itself rather in the irritability, emotionality and lack of continuous effort which come from a painful and nagging intracranial lesion than in the signs of psychological dissolution, as above described.

These remarks regarding the psychological symptoms of prefrontal lesions apply also to the fifth case in this paper, that seen by me with Doctor Mitchell. The views expressed regarding the cerebral representation of cutaneous and muscular sensibility and the stereognostic sense have further exemplification in the next case, which has in addition some interesting features as to visual and auditory localization.

*CASE IV.—Necrotic and Degenerated Area, Main Focus of Lesion Probably about the Junction of the Inferior Parietal Subparietal and First Convolutions; Localizing Symptoms: Astereognosis, Distortion in Pain and Temperature Senses, Word Deafness, Word Blindness, Akinetic Aphasia, Left and Right Hemiparesis and Late Hemiparesis; Operation: Recovery from Operation but Symptoms remaining about the Same.** The patient, forty-three years old, held an important teaching position and was a man of unusual intelligence and scientific attainments. The first symptoms of which we have any note was an attack in the early spring

*Mills, C. K. *The Nervous System and Its Diseases*. Philadelphia, 1898.

of 1898. When walking on the street one day he suddenly became dizzy, required support, and was left numb in the arm and leg of the right side. This numbness disappeared before he got back to his house. The numbness recurred at regular intervals after this time, lasting usually only for a moment, or for a few moments at most. He had no other symptoms of importance until he began to have headaches in February, 1900. The headaches were not continuous, but occurred at intervals and were not always severe. The attacks of numbness became more and more frequent. For a year or two before the onset of his attacks, in addition to unusual labor, he had been subject to a variety of worries. In addition to the symptoms above enumerated he was much of the time in a neurasthenic and depressed state.

My first note as to his condition were made June 2, 1900. At this time, if any true paresis was present in the extremities of the right side, it was so slight that it could scarcely be made out; but he presented in the right half of the body disorders of sensation, stereognosis, and co-ordination of a decided character, but differing somewhat in the upper and lower extremities. The pain and temperature sense were diminished in the face and upper extremity. Tactile sense was either present or so slightly diminished that in the man's condition the change could not be recognized. In the lower extremity the pain sense was distinctly diminished, but the temperature sense was not affected. Astereognosis as tested in the hand was present, but of slight, or at least moderate degree. He could make out objects by manipulation, but had some difficulty in doing this, and the difference in facility between the two hands was very noticeable. A study of the movements of the upper extremity showed some inco-ordination, and in dressing himself he had difficulty in fine movements such as those required in buttoning and unbuttoning the small buttons of his shirt, so that, although right-handed, he invariably resorted to his left hand in these procedures. Both the deep and superficial reflexes were at this time nearly normal, the only change being a slight exaggeration of the knee jerk. The Babinski reaction was not present.

A study of the man's speech mechanism was difficult in spite of the fact that he was highly intelligent and evidently very anxious to give all information possible. He was partially word deaf, word blind and letter blind, although the responses which were obtained in testing him were sometimes somewhat contradictory. He would recognize some words, usually those with which he was very familiar. Even when he recognized letters, he would generally call them all by the name of one letter. He was not object blind, but had marked verbal amnesia, in almost every case failing to name familiar objects, the use and meaning of which he evidently understood, a fact which he sometimes indicated by periphrase and at other times by pantomime; thus, he could not name a key, but said, "put it in," and indicated its use; he made the movements of putting off and on the lid of a box when a box was shown him, etc. When examined he sometimes became excited, confused and emotional, and occasionally made use of brief, but very strong words to express his disgust with himself.

Dr. de Schweinitz reported to me the results of his former examinations, which showed a high myopic astigmatism, and its usual intraocular and extraocular accompaniments; he also reported that the patient now had a distinct lateral homonymous hemianopsia, the diagrams of the fields accompanying his report. No positive optic neuritis was present at this time, and indeed at no subsequent period, although the conditions present were such as to indicate the possibility of a beginning nerve inflammation. The congestion of the optic discs present at previous examinations, which could probably be attributed to the disorder of refraction, was more marked on the left than on the right side. The iritic reflexes were unimpaired, and although the patient gave a history of temporary double

vision, he had no paretic ocular muscle. The examination showed that the hemianopsia was due to a lesion back of the primary optic centres, it not being accompanied by the changes in reflexes which occur when the lesion is in or anterior to these centres.

The patient grew worse as regards his visual, auditory and aphasic defects. The knee jerks became more exaggerated and the Babinski reflex appeared on the right side. The conditions as to sensation and co-ordination were emphasized. An illustration of his effort to write made June 16, 1900, is given below:

Only Sometimes you know this—Oh, it hurts like old Harry—every day better and better. Doesn't give me much—sick, is it—oh, no, not that—I forget what I want to say.

About June 23, 1900, he showed decided paresis of the right half of the body, and operation was decided upon. Dr. Keen performed the operation June 25, 1900. In consultation with Dr. William G. Spiller and Dr. J. W. McConnell, who had charge of the patient during my temporary absence from Philadelphia I had indicated as the proper place for operation the parietooccipitotemporal junction, the position on the lateral aspect of the brain where the three lobes come together. My idea was that the skull opening should cover the posterior extremities of the two parietal and the first temporal convolutions, and should extend backward far enough to include the anterior portion of the lateral aspect of the occipital lobe. The so-called angular gyre would of course be included in the opening. In this way it would include the centres for word hearing, word vision, and in part those for muscular and cutaneous sensibility. The position of the opening was therefore more posterior and inferior than in the three previous cases. The reasons for this are evident. In the first three cases disorders of cutaneous or muscular sensibility, or both, with late paresis or paralysis were present, but no word deafness, word blindness, nor hemianopsia. Paresis came on late in this case as in the others, but marked visual, auditory and amnesic disorders coexisted with the sensory, stereognostic and inco-ordinate phenomena comparatively early. Operation was performed by Dr. Keen June 25, 1900.*

The skull was opened with the centre of the flap about an inch or an inch and a half above the external auditory meatus, and as soon as the brain was exposed a very abnormal condition was detected. In the area in which it had been expected to find the focus of disease the brain was of a peculiar color as Dr. W. J. Taylor, who assisted at the operation, expressed it, it had the appearance of baked custard. It resembled baked custard both in color and consistence. It looked like pus, but was solid. The opening, which was originally comparatively small, was extended until it was from before backward about three to four inches. A large part of the brain was thus exposed, but even this was insufficient to uncover the whole altered area. The diseased portion seemed to be somewhat pyramidal in shape, with the base of the pyramid toward the occipital pole. The blood vessels supplying the area were thrombotic. It was impossible to remove all the diseased tissue, and Dr. Keen decided that it would be unwise to make the opening larger, even though the whole diseased area had not been exposed. He removed possibly an inch or an inch and a half of the diseased tissue in what seemed to be the first temporal convolution, but the convolutions could not be accurately determined. The tissue removed was semi-solid, and when a part of it was placed in a napkin and the two sides of the napkin laid against one another and then removed, the slight pressure so produced made the pathological tissue closely resemble pus. Microscopical examination failed to show any evidence of pus or tumor. The vessels were greatly diseased, some of them were completely closed; an intense round cell infiltration was found around the small blood vessels; a considerable amount of altered blood pigment was also seen, this indicating the existence of old hemorrhages. Dr. Spiller was inclined to believe that the condition was one of thrombosis; that the early symptoms were dependent on imperfect nutrition of the parietal lobe; that the symptoms which developed acutely about three months before the operation were due to thrombosis of the branch of the Sylvian artery supplying the first temporal convolution and

*This case has not hitherto been published, and I shall withhold its complete history and publication until after developments render certain the nature and extent of the lesion, or the opportunity to determine these points is lost. The patient first consulted me about May or June, 1900. In the month of April previous he had consulted Dr. S. Weir Mitchell, and had also at that time, at Dr. Mitchell's request, been examined by Dr. George E. de Schweinitz. Dr. de Schweinitz made other examinations for me previous to the operation, and I am indebted both to Drs. Mitchell and de Schweinitz for valuable notes.

*The account of the operation and of the condition of the brain presented by the brain when exposed, and of the microscopical findings, has been prepared from a report furnished to me by Dr. Wm. G. Spiller.

parietal lobe; and that the weakness of the right arm, which also came on suddenly, was the result either of thrombosis of the branch supplying the arm centre, or of hemorrhage occurring within the softened brain tissue, thereby producing pressure on the arm fibres within the internal capsule.

It should be noted here that numerous examinations made both before and after the operation showed the presence of a distinct amount of albumen and, at times, hyaline casts in the urine. The amount of the albumen varied somewhat, but in nearly every instance it was present, at least in the examinations made before the operation. The bearing of these facts was recognized when the operation was determined upon, but it was thought that on the whole the chances were in favor of a neoplasm, although other diseased conditions of vessels and brain tissue might also be present. Thrombosis, or obliterative endarteritis, such as not infrequently accompanies chronic disease of the kidneys and cardiac degeneration, may be the chief lesion, but it is certainly unusual to find one area of the brain after another becoming necrotic and degenerating in the fashion that it would seem occurred here, if a tumor was not present.

For the purposes of this paper, it is not necessary to go in detail into the history of this case subsequent to the operation. Right-sided paralysis was at first almost total, as was also aphasia and the auditory, visual, sensory and other defects studied before the operation. Some necrosis of bone with discharge of pus and debris occurred at times for several weeks after the operation, but later the wound got into good condition. The hemiplegia present after the operation has improved to such an extent that on two occasions the patient has come to my office in the city from his residence, a distance of eleven miles. He has made some, but not marked, improvement in his aphasic symptoms, other conditions remaining much the same as before the operation. It is not improbable that the pathological processes present for months before the operation are still going on, and the case has not a hopeful outlook. The case is briefly recorded here simply with the view of teaching its lessons with regard to focal diagnosis.

A fifth case was within a few months seen by me in consultation with Dr. S. Weir Mitchell and Dr. J. K. Mitchell. I examined the patient once the day before operation. Dr. J. K. Mitchell will publish a full report of this case. The general symptoms clearly pointed to brain tumor, which was diagnosed by the Doctors Mitchell, who suggested operation. My views as to the location of the tumor, and the facts on which these were founded, were as follows:

"The history and general symptoms indicate clearly that the case is one of brain tumor, the occurrence of one or more convulsions and the recent development of optic neuritis clinching this diagnosis. The psychical symptoms, under which head his lack of the power of attention, and a certain perverseness with a tendency to delusion are prominent, point to the perfrontal region. His long semicomatose or semisomnolent attack may also have its partial explanation in a lesion well forward in the brain. The paresis of the right upper extremity and of the face, which is slight and of late development, is probably a pressure symptom. His aphasia and agraphia are probably partly pressure and partly invasion symptoms. The agraphia is certainly the most interesting clinical feature. In general terms it belongs under the head of motor agraphia, and a study of his writing gives some support to the view of those who have said that the so-called motor graphic centre might perhaps be better called an orthographic centre.

He tends to repeat letters, syllables and words in writing, misspelling both common and proper names, evidently at times recognizing his errors and attempting by erasures and rewriting to correct them. On the negative side he is not word deaf, word blind nor letter blind; his speech aphasia is not of the form of a jargon aphasia; hemianopsia is not present, and he has no disturbance of common sensibility or of the muscular sense.

I would localize the growth in the left perfrontal region, the probabilities being that it is subcortical in origin, and that it is extending backwards, so as to gradually involve the second and third frontal convolutions. If this is correct trephining should be with the view of exposing the left half of the brain from the central fissure as far forward as the surgeon could safely expose with one osteoplastic operation."

The operation by Dr. Keen revealed the growth in the location indicated, although it did not prove to be subcortical in origin. Several facts are notable, (1) the absence of sensory symptoms, astereognosis and ataxia; (2) the absence of paresis or paralysis until late; (3) the presence of a peculiar form of agraphia or orthographia; and (4) the presence of psychical symptoms indicating more or less mental degradation or psychical dissolution.

Owing to excessive hemorrhage, it was not possible to conclude the operation by removing the growth. The patient died a few hours after the operation.

A few weeks since (February 25, 1901) I had the privilege of seeing a tumor removed in a sixth case from the motor region of the right hemisphere by Dr. William J. Taylor. The patient had been under the charge of Dr. Wharton Sinkler and Dr. T. C. Potter, and was seen by me in consultation with these physicians prior to the operation. My views as to general diagnosis and location were confirmatory of those held by Drs. Sinkler and Potter, namely, that the lesion was a tumor and was largely, if not entirely, confined to the motor zone. The patient had no objective sensory symptoms, although she at times complained of a numb feeling in the left side of the face, left arm and left leg, which were paretic, the loss of power being marked in the lower extremity. She had several convulsive seizures chiefly affecting the limbs of the partially paralyzed half of the body. All the deep reflexes on the left side were increased, persistent ankle clonus being present. The Babinski phenomenon was elicited on the left side. Head ache was not conspicuous, but vomiting occurred, and double optic neuritis was present. A full account of this case will be published by Dr. Sinkler, who has kindly permitted me to make this brief reference to it in order to compare the localizing phenomena with those presented by the other cases included in this paper. The most notable point is that objective symptoms referable to the areas of muscular and cutaneous sensibility and the special senses were absent, excepting of course the optic neuritis which has no localizing value.

The following are some conclusions to be drawn from a study of the foregoing cases:

The diagnosis of the existence of a brain tumor can sometimes be made even in the absence of most of the general symptoms, such as optic neuritis, headache, vertigo, and vomiting, chiefly by the close study of localizing and invasion symptoms.

Emotional states, even hysterical stigma, are sometimes present in cases of brain tumor, and must not be given too much weight in differential diagnosis.

Tumors of the posteroparietal region, and especially of the superior parietal lobule (parietal of Wilder), give as their most important localizing symptoms disorders of cutaneous and muscular sensibility, and especially astereognosis; other symptoms often present in such cases are the result of compression or invasion of adjoining regions.

Tumors and other lesions implicating the angular gyre and the regions adjoining (the subparietal, first temporal and mediooccipital convolutions), give as their main localizing symptoms word deafness and word blindness, with the usually accompanying speech disturbances, lateral homonymous hemianopsias and disorders of cutaneous and muscular sensibility, including astereognosis. Although it is possible that these disorders of sensibility in the case cited may have been dependent upon invasion of the superior parietal lobule.

Just as the centres for hearing, vision and speech are more highly differentiated in the left hemisphere, so it is probable that the stereognostic sense is more highly evolved in this hemisphere.

A tumor strictly confined to the motor regions does not give objective sensory phenomena of a persisting character; the localizing symptoms of a growth so situated are motor, chiefly paralysis and monospasm, with also exaggerated deep and superficial reflexes.

In tumors of the motor subcortex tonic spasticity is usually a marked symptom. Paresis or paralysis, and exaggerated reflexes, with monospasm or unilateral convulsions, may also be present.

Tumors of the prefrontal region, by which is meant the region entirely cephalad of the motor zone, chiefly give psychical symptoms of an especial character; when the tumor is situated on the left side, motor agraphia (or orthographia) and motor aphasia are usually present because of the compression or invasion of the posterior portion of the second frontal and of the third frontal convolutions; paralysis and other motor symptoms are often present late because of encroachments upon the motor region.

NON-SURGICAL TREATMENT OF FIBROID TUMORS OF THE UTERUS.*

AUGUSTIN H. GOELET, M. D.,

Professor of Gynecology, New York School of Clinical Medicine; Consulting Professor of Gynecological Electro-Therapeutics, International Correspondence Schools, Scranton, Pa.; etc.

The question often arises—What may be done for uterine fibroids where operation for their removal is not feasible or is refused, and in what class of cases will non-surgical treatment be attended by results that would justify its adoption? These are problems that not infrequently confront the general practitioner, and he is expected to decide the question in the interest of his patient, without much to guide him. He should therefore be correctly informed upon these issues.

Unfortunately the truth has been over shadowed by the strenuous efforts to establish firmly, the feasibility and comparative safety of radical measures in these conditions, and non-surgical treatment has been made to appear incompetent. Likewise the indiscriminate application of electricity to fibroid conditions, both where it was appropriate and where it was not, led to failures that have operated seriously against it. There is much to be said in favor of both methods, and there are cases where the indication for each is sharply defined. This then is the point at issue—When is

surgical intervention positively indicated and when may non-surgical methods be adopted with any promise of success?

Pedunculated fibroids both subperitoneal and submucous never yield to non-surgical measures, and they should be removed when discovered. The same may be said of interstitial growths that have attained sufficient size to cause the uterus to rise in the abdomen above the umbilicus. Fibrocystic tumors are another class that demand removal since conservative methods are of no avail.

It is true that much may be done to relieve the pain of large interstitial growths when their removal is not practicable. The relief thus obtained may be only temporary, yet it adds greatly to the comfort of the patient, and should be advised when extirpation is out of the question.

The class of tumors where non-surgical treatment may be expected to accomplish satisfactory results and is therefore advisable, are both fibrous and myomatous growths of the interstitial variety, that have not attained sufficient size to cause the uterus to rise above the umbilicus. The smaller the growth the better the chance of obtaining success with this plan of treatment. Hence the question often arises, should these growths be attacked when they are first discovered, or should they be disregarded if they are not producing inconvenience. Growths of this character are often discovered when they are producing no symptoms, and unfortunately it has been the custom to disregard them.

My observations, which, have been by no means limited, have led me to decide in favor of active measures for the arrest of these growths and their possible dissipation whenever they are detected, and when they are small, even if they are causing no inconvenience.

First—Because they continue to grow (though slowly in some instances) if nothing is done, even under the most favorable conditions.

Second—Because the treatment, if properly carried out by one competent to employ it, cannot possibly be productive of any harm, but on the contrary, if it avails nothing more, brings about a condition that will facilitate extirpation of the growth should it subsequently become necessary.

It is urged therefore that the patient be given the benefit of non-surgical treatment in those cases of fibroid growths of the uterus where unprejudiced observers have decided that there is a reasonable promise of success.

It must be borne in mind that fibroids are not infrequently found where, either because of some constitutional defect operation for their removal would not be safe, or the patient may positively refuse to consent to the operation, yet they are producing serious inconvenience. In these cases it would be most unwise to refuse to give them the benefit of treatment that would certainly palliate the symptoms and possibly relieve them, even though such relief may not be permanent. In such cases therefore non-surgical treatment is to be regarded as a necessary alternative, and should not be withheld.

Foremost among non-surgical measures for fibroid tumors of the uterus, is electricity. Both the

*Read before the Section on Diseases of Women at the third Pan American Medical Congress at Havana, Cuba, February 4th to 7th, 1901.

galvanic and the faradic current and even static electricity may be employed with benefit.

It is the electrolytic action of the galvanic current that is relied upon mainly to reduce the size of the growth, and cause its dissipation and when it fails to accomplish this result it is a material aid in relieving the symptoms, particularly pain produced by pressure and congestion. It also stimulates absorption of exudates, and removes many of the adhesions, this latter result being accomplished by shrinkage of the mass from contact with adjacent structures to which it has become adherent and consequent stretching and giving way of the adhesions.

Despite assertions to the contrary, electricity *per se* does not produce adhesions. Employed incompetently and without proper aseptic precautions a periuterine inflammation may be excited, resulting in adhesions, but that would not be the fault of the agent.

The method of application will depend upon the character and structure of the growth and the symptoms it is producing. When the tumor is a hard fibrous growth, the negative pole is to be employed, an uncovered metallic electrode being introduced into the uterus. This will constitute the active pole, and the electrode may be made of any material, because it is not acted upon by this pole. Copper is to be preferred because it may be readily bent to suit the curve of the canal. The ordinary uterine sound, insulated to within three or four inches of the point by slipping a piece of rubber tubing over it, makes an excellent electrode. The external or indifferent electrode, is to be placed upon the abdomen or back as is best calculated to include the main part of the growth between the two electrodes. This should consist of a pad made of several layers of thick felt thoroughly wet, and having the surface soaped to diminish resistance. It should be as large as can be conveniently applied to distribute the current and lessen the resistance.

The most satisfactory method of introducing the electrode into the uterus, is along the index finger in the vagina as a guide. But strict asepsis must be observed throughout every detail of the procedure. The hands should be sterilized by scrubbing them for five minutes with Synol soap, and the electrode must be sterilized by boiling in a 2 per cent. solution of the same for three minutes, after it has been scrubbed with a brush; or it should be passed several times through an alcohol flame, or that of the Bunsen burner. The vulva should likewise be scrubbed with Synol soap, and the vagina should be irrigated with at least two quarts of a three per cent. solution of the same, employing the distention method of irrigating. This consists in inserting the vaginal nozzle and compressing the labia, until the vagina becomes distended, then releasing the pressure and permitting the accumulated fluid to escape with a rush. This should be repeated until the reservoir is exhausted. The reservoir should be placed high, at least five feet above the table upon which the patient rests.

When zinc or other oxidizable electrodes are used, they should be scrubbed with a nailbrush on a cake of fine Sapolio soap, to clean and brighten the surface.

When there is hemorrhage or profuse or pro-

longed menstruation the positive pole is to be employed in the uterus instead of the negative and the electrode should be of platinum or zinc; preferably the latter, because the oxychloride of zinc that is liberated by the action upon the metal is more active in controlling the bleeding. After the bleeding has been permanently controlled the negative pole should be substituted for the positive.

Soft myomatous growths should have the positive pole applied to the interior of the uterus; and zinc electrolysis, secured by means of an electrode made of this metal, gives better results than simple positive electrolysis with the platinum electrode.

When these tumors are favorably situated, so as to permit the application of the current directly to the structure by puncture into it through the vagina, if judiciously employed, the result will be more prompt and more pronounced. The puncture is to be made with a steel needle, of small diameter, to a depth of 1-2 or 3-4 of an inch. But this method of application should never be attempted unless the puncture can be accomplished without the risk of wounding the bladder, rectum, uterine artery or ureter; and never without observing the strictest aseptic precautions, both at the time and subsequently, until the puncture has healed. There is no doubt that the application of the current in this manner, directly to the structure of the growth exerts a more decided action upon it than when it is applied through the uterus.

The application of the galvanic current through the vagina by means of the cotton covered ball electrode, can only exert a feeble electrolytic action upon the tumor, therefore it is of little value, except to relieving congestion.

The strength of the current to be employed will vary with the individual susceptibility. Usually the strength of the application of the negative pole to the interior of the uterus may be from 50 to 100 M. employed for ten minutes each time, and the application may be repeated every second or third day if the treatment is to be continued for a short period (one or two months). It is better to employ active treatment of this character for a period of two or three months, then discontinue it for two or three months and observe the result, repeating the applications if it is favorable.

The strength of the application of the positive pole when the zinc electrode is used should not exceed 50 or 60 M. employed for ten minutes.

The strength of the current used for puncture through the vagina should be 50 to 100 M. continued for ten minutes. The next puncture is not to be made until the previous one has healed. Then the puncture should be made in a different location.

The apparatus required for this treatment is much less expensive than is generally supposed. Sixty dollars would furnish a complete outfit for administering the galvanic current. There will be required 40 Laclanche cells, a current controller, a reliable meter, and the electrodes with conducting cords. Any dealer will explain how the cells should be set up and connected with the meter and controller in the circuit.

The faradic current is to be regarded as most effective for relief of pain and congestion. Though some reduction in the size of these growths has been reported from the use of this current, I am in-

clined to attribute this wholly to a restriction of the capillary circulation which can only be transient because it is powerless to remove the conditions that produce the increase blood supply to the tumor. The method of application is with a metal ball electrode in the vagina and a large dispersing electrode on the abdomen. The current should be as strong as can be comfortably borne without producing pain or discomfort. The application should be continued for at least 15 or 20 minutes, and should be repeated every day or every second day, as required to afford relief.

Static electricity is useful for relieving pain but cannot be expected to bring about any material change in the growth itself. Both the static spark and the static induced current may be employed with benefit. The spark is to be employed to the surface of the abdomen through the clothing, but the corsets should be removed because of the steels. The static induced current may be employed with one electrode (a metallic ball) in the vagina well up against the vault, and the other over the tumor on the abdomen. The external electrode should be a felt pad as large as can be conveniently applied so as to include as much surface as possible. Both electrodes may be applied to the external surface—one on the abdomen and the other on the back,—but the result is not so good as where one electrode is applied against the tumor in the vagina. By preference the vaginal electrode should be connected with the positive pole.

Ergot administered internally is certainly a valuable auxiliary in some instances. It acts by stimulating contraction of the muscular structure of the uterus and by compression of the blood vessels, diminishing the supply of blood to the growth. It also has a controlling influence upon bleeding from the endometrium which is sometimes an annoying symptom. In two instances at least I have known its influence combined with that of galvanic applications to the interior of the uterus to cause a breaking down of the intervening wall with sloughing of a large interstitial fibroid which was subsequently delivered successful, through the cervix, both patients making a satisfactory recovery. The combination of Liquor Sedans with Ergot acts well in painful conditions.

I have found the iodide and bromide of potassium useful sedatives in these conditions and they are certainly a material aid in some cases. They are usually administered five grains of the iodide with ten grains of the bromide in water three or four times a day.

Arsenauro (the bromide of gold and arsenic) is a most valuable internal remedy in these fibroid cases. It not only counteracts the anemia, but arrests the bleeding, effect in diminishing the menstrual flow where it is excessive is certainly very marked. In addition it affords relief by exerting a distinctly local sedative action, thus relieving pain which is so often an annoying symptom. These patients build up astonishingly under it when it is continued at the maximum dose for several months. The method of administration is to begin with six drops in water three times a day, after meals, and increase the dose one drop every day until the dose reaches sixteen drops, then continued it at this dose.

Recent observations have led me to conclude that interstitial fibroids of moderate size do sometimes disappear under the influence of electricity, aided by the internal remedies enumerated above. During the past year I have observed such tumors disappear in three cases and many others have diminished very much in size. Prior to two years ago I was led to make the statement that I had never seen a fibroid removed by electricity, except where it had caused sloughing and a discharge of the mass through the cervix. But recent observations have compelled me to change my views. Like others, in the beginning I was induced to try the benefit of electricity in all varieties of fibroids, because at that time their extirpation had not been demonstrated to be a safe procedure. Now, however, the limitations of electricity have come to be better understood and by restricting its use to those cases where it has been observed to yield results, and operating, where permissible, in those cases where it could not be expected to accomplish anything, there are now fewer failures and consequently more satisfaction in dealing with these cases.

AKROMEGALY, WITH REPORT OF TWO CASES

W. G. SHALLCROSS, of Elwyn, Pa.

Assistant Physician Pennsylvania Training School for Feeble Minded Children.

Owing to its obscure etiology, the wide distribution of its lesions, and a perversion of the natural laws of growth, akromegaly has baffled while inviting curious research.

It remained for M. Pierre Marie, through his studies of two singular cases in the wards of Charcot in 1886, to first point out the way. By observing similarities there presented, he was enabled, after careful study, to associate the symptoms complex with a hypertrophy of the pituitary body. With this discovery there was awakened great interest in the anatomy and physiology of this body, so that to-day its structure, nerve and blood supply and diseased state in many conditions are now fairly well understood.

Of the cases since reported, approximating closely on to three hundred, a sufficient number have been so amplified by patho-anatomical studies as to establish certain facts more or less constant.

The pituitary body is regularly found to be diseased, and generally its anterior or glandular portion; changes in the secretion of the thyroids, hypertrophy or atrophy rarely normal, occasional persistence of the thymus gland, and changes in the sympathetic nerves and ganglia.

On the other hand, the normal function of the pituitary body is absolutely unknown. That it has been found disorganized, hypertrophied, or probably absent without the symptoms of akromegaly, is likewise proven, and thus an accidental coincidence of its disease in these cases lends only to an hypothesis.

The other ductless glands need not be further considered: (c) as Burr points out, there is not a single one in the body which has not been found to be diseased in some of these cases, and it is more than probable they are only of secondary importance in accounting for the phenomena of akromegaly.

*These cases were exhibited by invitation before the Philadelphia Neurological Society April 23, 1900.

The theory of trophic neurosis, advanced by Von Recklinghausen and Holschewnikow, would seem to deserve a more careful consideration than is usually given in a study of these cases. By this theory it is held that the nervous system is primarily at fault, and the changes observed in the pituitary body and other structures are considered to be of a secondary nature. The reported autopsies, however, so far as I have been able to trace, add little or no weight to this theory. In many there is no mention made as to the condition of the nervous system, excepting the results of pressure through an enlarged hypophysis.

(f) Arnold and Dellemagne found, on several occasions, an asymmetrical degeneration of the posterior columns of the spinal cord. Marie Marinesco and Arnold found the spinal ganglia and sympathetics hypertrophied.

Clinically we are dependent at least for an early diagnosis, upon certain trophic changes, such as paresthesias and joint pains; numbness and tingling sensations in the extremities; hyperhidrosis, pigmentation and thickening of the skin; changes in the hair, nails and joints, and further study is needed along these lines before accurate conclusions can be reached.

The purpose of this paper is to present the record of two cases developing under daily observation during a period of about six years.

CASE 1.—S. B., male, aged eighteen years. High-grade imbecile, admitted in 1892 at the age of ten to the Pennsylvania Training School, made fair progress, soon learned to read and write, and was regularly promoted in his class for four years when the limit seemed to have been reached

Fig. 1. A case of Akromegaly.

and, mental development ceasing, he was transferred from the schools of the industrial department, where he has ever since proven a useful aid.

Shortly after this time he suffered from aural catarrh, which was merely a relapse of former trouble dating from early childhood. Three years previous he had what was thought to be rheumatism of the right ankle, and has since

had several recurrences. It is now presumable that these attacks were premonitory symptoms of the disease. In August, 1896, bursitis of the right knee developed. Rest and treatment soon effected an apparent cure, and a month later a relapse, the result of an injury to the same knee from a fall, again yielded to treatment, but after this muscular atrophy was noted, the knee began to enlarge through bony formation around the joint, and osteo-arthritis became pronounced. With this genu valgum slowly progressed. At present the trouble is much exaggerated, but there is little or no pain in this region. On bending the knee a grating and creaking sensation can be distinctly felt, and what appear to be small, loose or "floating bodies" detected.* Roswell Park (d) reports a similar interesting case. His, however, was a cystic tumor without bony deformity, which he evacuated, and removed five fibrous masses. One year later, August, 1897, abscess of the right antrum of Highmore developed. After perforating the cavity at the root of the second bicuspid tooth, irrigating and draining, recovery rapidly ensued. Shortly following his discharge from the hospital a marked change, both mental and physical, was noticed, and within a year, at the age of fifteen, the symptoms of akromegaly became apparent. He now began to grow rapidly, and a year later, when I first saw him, he had attained nearly his present size and stature, presenting all the symptoms of the disease. Kyphosis undoubtedly existed before the development of these symptoms, and even before his admission in 1892.

Abnormal development was first noticed through the frequent changes required in the size of his shoes. The hands were also found to be correspondingly enlarged, and he became very sensitive regarding their size.

FAMILY HISTORY: Born in Philadelphia May 18th, 1882, labor normal. Father 24, mother 20 at the birth of this, their first child. The father is below the average in intelligence, and deaf; he is a driver by occupation, and is still living. The mother died at the age of 25 of malaria. The patient has one brother living, fairly strong mentally and physically. Paternal grandmother died of consumption, maternal grandfather died of cancer of stomach.

PERSONAL HISTORY: The admission blanks, August 1892, describe him as follows:

Light hair, blue eyes, sight good, hearing a little affected. He is of the usual weight and size for his age. Ordinary shaped head, mouth always open, teeth good; has long features. In walking bends forward, and in speaking stammers a little. Is nervous, active, destructive, and heedless of danger. Commenced to walk at sixteen months; has had measles, whooping-cough and scarlet fever. Otitis media developed as a sequel of the latter disease when four years old, resulting in a chronic discharge from his left ear and in impaired hearing; mental degeneration is supposed to date from this period.

A physical examination was made March 27th, 1899, with the aim of studying future changes. (See Chart No. 1 of Measurements; also Plate 1 showing features and general characteristics).

PHYSICAL EXAMINATION: Age, 16 years ten months. Weight, 95.2 Kg., approximately, 210 lbs. Height, 190.6 cm., approximately 6 ft. 3 in. Hair, color chestnut-brown; on head it is coarse and dry. In axillary and pubic regions it shows no characteristic changes. The skin is paler than normal, and is appreciably thickened all over the body; on his face it is pigmented, and over his shoulders and lateral surfaces of chest and abdomen is thrown in rugae.

The expression of his face is dull; general muscularity and fatness diminished. There is marked cervico-dorsal kyphosis, slight scoliosis and right genu valgum. In June 1900, one year later, through the suggestion of Dr. Caspar W. Miller, X-ray pictures of his extremities were made. The trunk and jaw were too thick to obtain any clearness of detail, so this part of the investigation we were forced to abandon. The result, however, shows only a uniform hypertrophy, merely an exaggeration of the normal state. On this account the illustrations will be omitted. The ears are large and cartilages thick. The nose is very large, measuring 6.6 Cm. from frontal bone to tip, and 5.2 Cm. across alae. The nares measure 1.5 X 2 Cm. The septum is thickened and deflected toward the right. A large spur

(f) Oppenheim on Diseases of the Nervous System, P. 873.

(d) International Medical Magazine, Vol. 4, No. 1.

is seen on this side springing from the lower border of septum. Both the middle and inferior turbinated bodies are deeply congested and infiltrated.

The lips are thick, teeth normal in size and number. The alveolar processes are hypertrophied, the right curved inward (half saddle-shaped). The hard palate is deepened, the soft palate and uvula thickened. The post-nasal space is thereby much contracted. The tongue is long, broad and deeply fissured, measuring at its broadest part 7 Cm. It resembles closely this organ seen in the Cretin and Mongolian type. The voice is thick and guttural. The face is oval and prognathous. Malar bones massive. Inferior maxilla thick, and chin projecting, so that the lower incisors do not articulate with the upper, but are carried out beyond them slightly. His neck is thick and short, and the right thyroid body is distinctly enlarged and firm. (a) (Hutchinson, in an analysis of 218 cases, found this body enlarged thirty per cent., and atrophied in ten per cent.) The thoracic cage bulges forward, increasing the antero-posterior diameter materially.

The abdomen is pendulous and the breasts enlarged; (usually the latter, in females especially, are described as atrophied). The sternum and clavicles are very broad and thick. This increase in size of the latter is particularly marked on their inner thirds. The ribs share equally in this bony development, and at the sternal junction are noticeably beaded. The genital organs are hypertrophied.

megalic, is never complained of, and apparently is absent.

A full report of the examination of his eyes by Dr. J. Thorington is here given: S. B., age 18 years. Examination of eyes.

INSPECTION: Eye lashes, eye-lids and palpebral fissures apparently normal. Eye-balls are not prominent. Extraocular muscles normal and ocular excursions perfect. Corneas normal. Anterior chambers normal. Pupils are round, four millimeters in diameter. Irides react very sluggishly to light, convergence and accommodation.

VISION AND NEAR POINT. This is the same in each eye, vision being normal, V/V, and near point 9 Cm.

OPHTHALMOSCOPE: Right eye. Media clear. Disc large, slightly vertically oval. Choroidal ring all around the disc. Shallow physiological cup. Arteries smaller than the normal; relative proportion between arteries and veins in health. Veins slightly tortuous. The disc is decidedly pale in color and very few capillary vessels can be recognized. The direct and the indirect methods of examination, and also the plane and the concave mirror, show the characteristic atrophic nerve. The refraction is hyperopic about half a diopter. The left eye shows the same conditions as the right, except that the temporal side of the disc is heavily pigmented.

COLOR VISION There is no color blindness. The

Fig. 3. Fields of vision in a case of Akromegaly.

testicles firm. Auto-erotism, generally noted as being absent, has apparently in this case not diminished. When younger he was known to masturbate and to practice sodomy. At present he tells me he experiences nocturnal emissions. On one occasion spermatozoa were found in the urine.

The relation between his height and the stretch of arms, measuring from the tip of one middle finger across his chest to the other, as might be inferred, is markedly altered. Normally the stretch is approximately 5 Cm. greater; in this case we find the difference to be 18.6 Cm. (e) The length stretch index computed from this is 1.07. Normal approximately 1.02. Imbeciles .096 to 1.068.

The hands and feet are steadily increasing in size. He now wears a No. 15½ shoe.

Sensation, tactile, thermal, weight and pressure, and location are normal.

SIGHT: Subjective symptoms are still absent, excepting at night he experiences difficulty in finding his way about.

Headache, the commonest of complaints of the akro-

patient selecting the worsteds accurately and without hesitation in each instance.

FIELDS: The form field is contracted to within ten degrees of the point of fixation. The color field is smaller than the form field. This is the same in each eye.

DIAGNOSIS: Progressive double optic atrophy.

HEARING: This is about one-third normal in his left ear, and greatly diminished on the right side. He has suffered at various times from otorrhoea in both ears.

SMELL: The sense is lost on the left side, and apparently decreased in the right. He still can recognize the common essential oils and other odoriferous substances. Taste sense is not appreciably diminished.

MOTOR DISTURBANCES: His gait is slow and deliberate, and naturally abnormal on account of the right genu valgum.

Station and sway are normal.

Cutaneous reflexes normal.

TENDON AND MUSCLE PHENOMENA: The knee jerks are diminished, almost lost in the right. There is no ankle clonus. Toe, elbow, wrist and jaw jerk normal.

SECRETORY DISORDERS: There is marked general hyperhidrosis which is particularly increased on the right half of the body. When stripped, even in a comparatively cool room, great drops of sweat are to be seen trickling down the lateral surfaces of his chest from the axillary folds.

(a) Woods Hutchinson, New York Journal, March 12 1898.

(e) One hundred imbeciles were examined, many of them types of atavism for a comparison of indices with the following results: 10 per cent 1.083 26 per cent 1.071 18 per cent 1.018, 16 per cent .98. The highest 1.068. The lowest .96.

TROPHIC DISORDERS: The skin is generally thickened, and over the shoulders, sides of chest and lateral surfaces of abdomen it is thrown in rugae. Distinct linea striata are to be seen running inward and upward from crest of ilium. The nails are broad and flat, and finger tips square. Fleshy pads, so commonly described in this disease, are well shown in palms of hands and feet. Joint pains are constant. The right fingers are numb and tingle in the early morning.

TEMPERATURE: The axillary temperatures compared daily show a constant variation of about two-fifths of a degree higher on the right side.

PULSE: 86-98. The arterial tension is increased, and the coats are appreciably thickened.

Slight varices are noted in the legs.

HEART: The heart is hypertrophied. The apex beat is forcible in the sixth interspace and just outside the nipple line. Dullness extends upward to the third rib and at transversely two centimeters beyond the nipple line, and to the right border of sternum. The first sound is prolonged and dull. The second sound at aortic cartilage is accentuated.

RESPIRATION: 22-24, character abdominal. On percussion and auscultation the chest is negative, excepting there is marked dullness over the upper sternum. (b) Erb, to whom the credit is due, first pointed out this sign in akromegaly as suggestive of an enlarged thymus gland. He, supported by Shultz and Verstraeter, believed it to be characteristic.

Appetite is moderate, at times capricious. He does not care for sweets, and on diminishing the amount of sugar and starches in diet the traces of sugar found in the urine ceased altogether. On the other hand, when given an excess, the amount did not seem to materially increase.

LIVER: The liver is increased in size. The lower border is smooth and can be felt about 5 Cm. below the costal margin.

SPLEEN: This is enlarged and tender.

KIDNEYS. The right kidney cannot be palpated. The left kidney is distinctly enlarged.

URINE: Urine examination March 10th, 1900. Average daily quantity 2400 C. c. Reaction acid. Sp. Gr. 1.025. Sugar, albumen and acetone present in traces. Urea 2.6 per cent. The phosphates, chlorides and sulphates were in their normal relation. No diacetic acid. Microscopically casts, granular and hyaline. Crystal calcium oxalate.

October 15th. Average daily quantity 6810 C. c. Reaction acid. Sp. Gr. 1.010. No sugar. Albumen .030 gm to 500 C. c. Acetone traces. No diacetic acid. Phosphates, chlorides, sulphates normal.

Microscopically—Casts hyaline; crystal calcium oxalate.

GLANDS: Not enlarged.

Blood Examination March 10th, 1900.

Red cells.	5,265,000
White cells.	8,000
Hemoglobin.	85 per cent
Eosinophile cells.	1.66 per cent.

October 13th, 1900.

Red cells.	4,760,000
White cells.	6,400
Hemoglobin.	85 per cent

Differential Count.

Polynuclear neutrophils.	63 per cent.
Small lymphocytes.	23 per cent.
Large and transitional.	9 per cent
Eosinophiles.	5 per cent.
Number of cells counted	1165

CASE NO. 2.—P. K., age 20 years. Family history unknown. When admitted to the Pennsylvania Training School at the age of fourteen years he was classed as a middle-grade imbecile, unable to read and write. He was active, noisy and disobedient. His features were good stature and general muscular development apparently normal. When placed in school it was quickly found that his mental limit had already been reached; unable to concentrate attention, with no memory power, the lessons of one day, even after constant repetition, would be forgotten the

next. For manual arts he was equally incapable, but developing some aptitude for ordinary industrial occupation, he was, after two and a half years' trial, taken from the schools and put to work in the kitchen. At this time, August, 1896, he was of the usual size and weight of a lad of sixteen, and in vigor and strength was considered rather above the ordinary imbecile.

Fig. 2. A case of Akromegaly

This case represents a very early stage of the disease, and it is only of late I have been enabled to make a diagnosis. Among the imbeciles we have many abnormalities, so that one must consider what is representative of this type on the one hand, and on the other what is characteristic of a disease like akromegaly in its erethistic stage. Adolescence is reached; health and physical strength were, until the last six months, exceptionally good, and the course of the disease has not been marked by pronounced changes.

In December 1899 my attention was first drawn to his malady while he was suffering from a mild attack of influenza. He was then about six feet tall, face slightly prognathous, his hands unusually large, and he wore a No. 11 shoe. There was no kyphosis, no evidence of trophoneuroses, no apparent enlargement of the lower jaw. The urine and blood examinations were normal. Later he began to suffer occasionally from indigestion, muscular pains, principally in the thighs and legs, and headaches. Plaster casts of his hands and feet were made. In June an examination of his eyes and fields by Dr. Thorington was made and repeated seven months later for comparison. The cuts clearly illustrate the changes. (See also his report). X-ray pictures were also made about the same time, but these latter, as in Case 1, show the same uniform hypertrophy, and nothing characteristic.

Measurements of his body were likewise taken and compared later. The lower jaw is elongating, causing the teeth to protrude a trifle. The eyes and cheek bones are becoming more prominent, the lips thicker, and nose larger. The skin on the face is thick and pigmented. General hyperhidrosis is pronounced, although not nearly so much as in Case No. 1. A recent study of the urine shows advancing renal changes. Average daily quantity, 1675 C. c. Color, pale amber. Sp. Gr. 102°. Reaction acid. Albumen, acetone and indican present in traces; no diacetic acid, no sugar.

Microscopically—Hyaline casts and calcium oxalate crystals.

FIG. 1. Fields of vision in a case of Akromegaly.

Blood is normal. Axillary temperatures equal and normal.

Respirations 24 26, abdominal in type. Chest full and regular.

Reflexes normal.

The genital organs are hypertrophied. There is apparently no diminution in the auto-erotic phenomena.

Appetite moderate, stomach and intestinal tract presumably healthy. There is neither polyphagia or polydipsia. His general disposition is good, excepting when suffering from headache he is irritable and forgetful, as might be expected. Responding to military training, he carried himself well and was exceedingly erect; but latterly several interesting features are noticeable; he is beginning to stoop, has lost the sense of time in music, and there is progressive general weakness, and he is now easily fatigued.

His shoes have been recently changed for a size larger (No. 12), and the two casts made within an interval of seven months, of his right hand, are strikingly dissimilar.

Dr. Thorington's Report, June 1st, 1900. P. K., age 20 years. O. D. V.—V/V. O. S. V.—V/V. Pupils large, round, five millimeters in diameter. Irides react sluggishly to light, convergence and accommodation.

Ophthalmoscope shows medium sized nerves. Relative proportion between size of retinal arteries and veins is normal. The arteries are not narrowed, and veins are not enlarged. Both nerves appear normal. The refraction is hyperopic less than 1 D.

Fields show concentric contraction for form and colors; this is especially marked in the left eye.

Diagnosis: Beginning optic atrophy.

TREATMENT.

Only in Case No. 1 have I attempted more than a symptomatic form of treatment. We hope later to be able to report more fully on the value of the animal extracts.

S. B. has been taking an extract of the thyroid body for the past three months in daily doses increasing from fifteen to twenty-five grains, with so far no apparent benefit.

My thanks are due to Dr. Martin W. Br. Chief Physician of the Pennsylvania Training School, for his material assistance in working up these cases, and permission to make this report.

A CLINICAL NOTE ON INFANTILE SCORBUTUS.

WM. M. MASTIN, M. D.

of Mobile, Ala.

The recent paper by Dr. Griffith on infantile scurvy in *The Philadelphia Medical Journal* (February 2, 1901) suggests the report of four cases of this disease coming under my observation within the comparatively short period of the past six months, and which, I hope, will serve to emphasize his remarks relative to the frequency of the affection.

It is a matter of surprise that notwithstanding the rather numerous publications on the subject during late years, notably among which may be mentioned the article of Northop and Crandall, appearing as early as 1894, there is a decided misconception of the malady by the general practitioner, and especially so in confusing it with rheumatism. The impression seems to prevail among the profession that scurvy in the first years of child life is a very rare affection, and, on the other hand, that rheumatism in infancy is quite common. In reality the reverse is true, if I may judge from the published records and my own personal experience, although my work is largely surgical in character, and I am assured the observations of the pediatric specialist will fully sustain this opinion. Furthermore, there is scarcely a doubt that infantile scorbutus is rapidly increasing, due obviously to the more widespread resort to artificial feeding and the almost daily addition to the already vast number of commercial infant foods.

The subjoined cases combine several features of interest. They demonstrate that errors in the diagnosis of infantile scurvy are not confined alone to rheumatic affections, but may extend to the domain of surgical disorders—tubercular bone lesions, sprains and contusions; to the nervous system—disease of the cord; and even include hereditary syphilis.

They show also that scurvy may arise during the exhibition of several of the most popular artificial or prepared foods, and, in addition, what is of much consequence, that its occurrence under the use of sterilized milk must be undoubtedly conceded.

Again, one of the cases suggests the possible intimacy, or, at least, association, of infantile scurvy with a form of pernicious anemia, which, taken in connection with the recent observations in this direction, is of some importance.

CASE 1.—J. M., a male child 13 months old, was seen by me in consultation with the family physician on June 3rd, 1900. The child had been in failing health, as evidenced by loss of flesh, disturbed digestion, anemic appearance, fretfulness, etc., for the past three months, during the last eight or nine weeks of which time pain in and swelling of the lower extremities was noticed, the pain being greatly exaggerated on movement and handling. These symptoms were at first attributed to rheumatism, and the salicylates and kindred drugs were freely used.

As the disease progressed the swelling, pain and tenderness gradually increased, especially in the right knee and ankle and along the tibia, when the diagnosis was changed to that of periostitis of probable syphilitic nature. It was at this time that I requested to see the case. Examination now showed an extremely pale, emaciated and fretful baby, bearing the impress of suffering in its pinched features, indisposed to move, and crying out with pain when touched or handled. Both lower limbs were painful on movement and pressure, particularly over the tibial epiphyses, with swelling, thickening and some redness along the tibiae.

These symptoms were much more pronounced in the right leg. There was slight tenderness on pressure about the arms and hands, but no further implication was found in the upper extremities. There was no evidence of rickets. The gums were swollen, spongy, and ulcerated along the line of the upper and lower incisors. The child had been nursed at the breast for the first month and a half of life, but at this period the mother's health became impaired and her milk failed. Condensed milk was now substituted, upon which the infant seemed to thrive, and this, together with Mellin's food and occasionally feeding with farinaceous articles of diet, was the character of nourishment the child had received. On a diet of raw cow's milk combined with a moderate proportion of Mellin's Food, with orange juice daily administered, the scorbutic symptoms rapidly subsided and were entirely relieved. The condition of anemia, however, progressed unchecked, although reconstructives were freely employed. The child succumbed several weeks later to an attack of enterocolitis.

The noticeable facts in this case are that the disease was mistaken for both rheumatism and hereditary syphilitic periostitis; that it occurred whilst on a diet of condensed milk and Mellin's food; and thirdly, and of especial interest, its connection with a form of anemia most probably of a pernicious type.

The affinity between infantile scurvy and pernicious anemia was recently suggested by Dr. J. L. Duenas, of Havana, who reported in the *Archives of Pediatrics* January, 1901, an important and suggestive case where there was an intimate and probable etiological relationship existing between the two diseases. It is greatly to be regretted that careful blood examinations were not made in the case of J. M., but the character and persistence of the anemia, notwithstanding the prompt and complete relief of the scorbutic manifestations, leave scarcely a doubt as to its nature and association, particularly in the light of Dr. Duenas' contribution.

CASE 2.—Grace Van H., a female child ten month old, was brought to me from Jackson, Ala., August 10th, 1900, for trouble existing in the left hip joint, which had been diagnosed as tubercular. The child was born at term, of healthy parents, and was vigorous at birth. For the first month it was nursed at the breast, but at this time the mother suffered from an attack of fever, with checking lactation, a diet of Mellin's food and condensed milk was prescribed. This was the only food given and apparently it furnished all the necessary nutrition until about six weeks prior to its visit to Mobile. Then it was noticed that the infant was growing thin, losing color, becoming fretful, and the appetite diminishing. These symptoms somewhat increased for about two weeks, when it was further discovered that the left hip and thigh were painful and swollen. These were the symptoms present when I saw the case, and, in addition, it was found that the thigh was partially flexed on the abdomen and the entire limb rigid and almost immovable. There was moderate swelling about the joint including the thigh down to the knee, and the least movement, or pressure over this area of surface caused decided pain. At the first glance the symptoms were certainly those suggestive of hip disease, but a closer examination, together with finding that the tenderness also existed to a moderate degree in the epiphyses of the bones of both lower extremities, with a spongy condition of the gums and the anemic appearance of the patient was convincing evidence that the trouble was not simply localized, but dyscrasic in character. The food was changed to raw cow's milk, and the juice of an orange ordered to be given daily. Under these measures improvement took place rapidly, and within a period of ten days or two weeks the child had practically recovered.

The diagnosis of infantile scurvy in the majority of instances offers relatively but few difficulties, and the present case is interesting because of the somewhat obscure symptoms which characterized the onset of the attack. With the presence of pain in and slight swelling about the joint, flexed thigh

and rigid muscles, and the general depreciation of the child's health, it can be readily understood how one might be misled. But with the appearance of tenderness about the joints and bones of both limbs, with spongy and ulcerated gums, the diagnosis was quite apparent.

CASE 3.—P. H. B., male, one year old. This child was brought from the interior of the State and seen by me on October 18, 1900. The history of the case is as follows:

It was the first child, delivered with instruments, but healthy and vigorous at birth. For the first three or four weeks it received its mother's milk, but it did not thrive and improve in weight, and the physician in attendance advised a change to sterilized milk. This was done, and for several months thereafter improvement in nutrition was marked and the food seemed to agree most admirably. When the child was about seven or eight months old it was observed to be losing flesh and becoming languid, pale and fretful, but this was attributed to the warm weather, and the diet of sterilized milk was continued. These symptoms of depreciating health continued and increased until six weeks prior to the date on which I saw it. It was then noticed also that the movements of the child were quite feeble, especially of the lower limbs, and, although it had learned to stand with the aid of a support, the legs now gave way under its weight and it soon ceased to make such attempts.

It happened just at this time that the child slipped from a table on which it was sitting, and the nurse in catching it was thought to have wrenched its back, for it cried loudly and seemed to be in pain for some hours. After this it refused to make any effort whatever at sitting or standing, and cried when handled or moved. An injury to the spine was believed to have been sustained, and the parents brought it to Mobile. Another physician was now consulted who diagnosed a serious cord lesion and advised placing the child under the care of a neurologist, but before doing so I was asked to see it. I found the infant anemic and weak, with the facies of illness, and apparently having lost entire motion of the lower extremities. It was quite thin, especially the legs, and the joints stood out prominently.

The slightest movement produced intense pain—the child almost swooning when turned about for examination—and there was decided tenderness over the hip, knee and ankle joints and along the tibial crests, but scarcely any swelling or thickening in these localities. The arms and shoulders were also somewhat sensitive and painful. The gums were distinctly ulcerated about the upper incisors. The appetite was poor. Infantile scorbutus was diagnosed, and a food of raw cow's milk combined with a small amount of Mellin's food, and a liberal quantity of fruit juice, was suggested. In addition iron internally and inunctions of cod liver oil was advised. Improvement was astonishingly rapid; within a week after the adoption of these measures the child was almost free of pain and was rolling over in bed and using its legs vigorously; and each day added to these strides towards recovery until at the expiration of a month it was allowed to return home perfectly well. The further progress of the case was uneventful.

I wish to call attention to the development of scurvy in this case during the use of sterilized milk. I know quite well that this is a disputed question, and that some observers maintain that heating or sterilization has no effect whatever upon the nutritive qualities of cow's milk. But if we admit, as the present status of our knowledge seems to demand, that the etiology of scurvy is largely dietetic, then in this instance where no other food of any character except sterilized milk was employed and where the child promptly recovered after the diet was changed to milk in the raw state, we are forced to the conclusion that the act of sterilization was the prominent or causative factor. It is indeed true that cases are recorded where scorbutic children have been cured simply by the exhibition of fruit juices without change of the former diet, and it is, of course, difficult to determine which was the

actual therapeutic agent in a case where both the use of orange juice and a change of food had been made. But that the process of heating does produce alterations in milk which lessen or seriously impair its food value, I feel convinced, and even if it cannot be proven that milk thus prepared is a positive or direct cause of scurvy, there is sufficient evidence to render the probability of such a power very strong, which should be fully recognized and a warning note sounded in the matter. This is all the more essential on account of the very extensive use of sterilized milk, not only as an infant food, but also as a diet in general illness, and especially diseases of long duration.

This case also presented obscurities in the diagnosis.

The fact that probable injury in the form of a wrench or sprain of the spine had been received, followed almost immediately by apparent total loss of movement of the lower limbs, rendered it quite probable that traumatism to the cord had been received. With the continuance of these symptoms of paralysis, strongly suggestive of a poliomyelitis, it is not surprising that the error of regarding the trouble as located in the cord was made.

CASE 4.—On February 12, 1901, in consultation with the family physician, I saw I. J. D., a female child, of healthy parents, 13 months of age, whose history and condition were as follows: This child was vigorous at birth, and for the first month was breast fed; but the mother's milk now failing, prepared or artificial food was resorted to. In the beginning this consisted of condensed milk, which at first seemed to agree, but digestive disorders soon appeared and it was changed for Mellin's food. The gastric and intestinal troubles continued, however, and Horlick's food was substituted, and on this diet the digestion improved and the intestinal irregularities were corrected. This had been the food employed for the greater part of the child's life and was being given when I was consulted. The present affections began about eight weeks before, commencing with pain, tenderness and swelling in the right ankle, then rapidly extended to the knee and hip of the same side, and within the period of a week had invaded the left hip. The pain was quite severe, and was greatly exaggerated upon the least movement or handling, necessitating carrying the infant about on a pillow. As these symptoms progressed the general health of the child became somewhat involved, there being languor, fretfulness, pallor, and moderate loss of flesh, but the nutrition was not greatly disturbed and the appetite remained good. Three weeks later the gums showed a line of ulceration along the incisors and were spongy and inclined to bleed. The initial symptoms quite naturally suggested rheumatism, and anti-rheumatic treatment was instituted, but no benefit resulting from these measures, and the local condition of swelling, thickening, etc., increasing, the physician decided that there must be a periosteal or bone lesion of some character. My examination disclosed the condition as above described, with the addition of finding enlargement of the joints named, and marked thickening, induration of a brawny type, and a rather purplish color of the tissues along the course of the tibiae.

No indications of rickets were present, and the nutrition of the child was but little impaired. The entire complexus of symptoms was clearly those of scurvy, and on a diet of raw cow's milk, with orange juice liberally given, together with syrup of iodide of iron, the symptoms yielded promptly, and the child is now rapidly recovering.

This case does not call for comment other than to note the close resemblance of the early or initial symptoms to acute articular rheumatism, and then in the later stages the simulation, in its local appearances, of osseous and periosteal disease.

Next to rheumatism it is very probable that in-

OPERATIVE TREATMENT FOR PROSTATIC HYPERTROPHY.

By RAMON GUITERAS, M. D.

of New York.

In looking over the history of the last century we find constant references to prostatic hypertrophy, increasing in number and value as the years roll by until the days of Thomson, Mercier and Socin, when some definite idea began to dawn upon surgeons interested in prostatic work, and many ingenious devices were introduced.

First among these were the various palliative methods; then those of drainage; the methods causing absorption of the gland or reducing the obstruction by dilatation; methods of diminishing the size of the gland by the use of the galvanic current, by injections of various fluids into the gland, by ligating the vessels supplying it, by castration or by ligating the vas deferens; operations tending to destroy the obstructing parts; and later methods of removing the entire obstructing body.

The palliative methods I will not mention, as they are fore fitting for a paper on general treatment of prostatic disease, I will speak briefly of operations for drainage in this condition. It is resorted to in two ways, 1st. by the perineal method in which a perineal urethrotomy is performed, and a tube inserted into the bladder. This is also more of a palliative method to relieve the pain, tenesmus and frequency accompanying cystitis

and posterior urethritis, and is spoken of in an operative way on account of the urethrotomy necessary. 2nd. Drainage suprapubically by means of a cystotomy is resorted to in a similar way for the relief of symptoms, especially if there is troublesome retention, also when the obstruction is complete and catheter life is attended by distress and complications, in which latter case a permanent drainage may be established and a tube worn for the purpose of emptying the bladder. It is interesting in some of these cases which have been regarded as hopeless, to notice how much the prostatic oedema will subside after the operation so that after a certain period spontaneous urination or easier catheterization may follow.

Dilatation with steel sounds, or dilators, every four days has been recommended by many practitioners. It may be of some value at the start associated with hot rectals and massage. Bellfield says that he has been convinced by experience of the value of this neglected measure to facilitate the exit of urine. Personally while I have never been much impressed with this method, and I do not now consider it in the light of radical treatment, I have nevertheless recently tried it in a small number of cases in which there was considerable bladder irritation, accompanied by a little residual urine (where the prostates were beginning to enlarge) complete relief to the symptoms from which they were suffering. I doubt, however, in those particular cases if the prostate was large enough to have caused sufficient obstruction to warrant any of the so-called radical methods now in vogue. My method of treating them was first hot rectal-saline irrigations by the recto-genital tube every night, accompanied by massage of the prostate twice a week, and later by stretching with

*Read before the Third Pan-American Medical Congress, Havana, Cuba, February 5, 1901.

a Kohlmann dilator after each massage, the dilation being followed by urethral irrigations of a silver solution.

Galvanopuncture has been recommended by Biedert and others, but is now never used. A platinum needle attached to the negative pole of a galvanic battery, and insulated up to within $1\frac{1}{2}$ centimeters from its point is carried into the rectum, inserted to a depth of $1\frac{1}{2}$ centimeters into the prostate and the current allowed to act for 2 to 5 minutes at a strength of 10 millamperes, gradually increased to 25 millamperes. The needle is then partly withdrawn and inserted through the same puncture in another part of the gland, and the current is again allowed to work from 2 to 5 minutes. The sittings are repeated at proper intervals from 10 to 20 times. These proved to be of very little value because they are exceedingly painful to the patient, and there is danger of cauterizing the gland quite severely.

The same may be said of parenchymatous injections which have also been tried by Heine. He used a hypodermic syringe containing a solution of iodide of potassium two parts, tincture of iodine 30, to 60 of water, injecting it into the gland every 8 to 14 days. Ergot and absolute alcohol have been used. He states that there were favorable results in these cases, but they are not without danger as abscesses may follow.

Ligation of the internal iliacs was recommended by Blier as an operation which would cause atrophy of the gland. It has been performed by numerous surgeons, but the benefit derived is never sufficient to counterbalance the danger of such an extensive operation.

Castration, an operation devised by one of our most eminent surgeons with the object of causing atrophy of the prostate has now been discarded, as it was found that the results were in many cases not permanent, while the mortality was from 16 to 18 per cent., and in the cases surviving some became maniacal, some melancholic, while many others were neurasthenic or otherwise lost their mental equilibrium.

Vasectomy was then advocated, it being held that if the ducts were resected it would have the same effect in causing the diminution in size of the gland that the removing of the testes would. It was also argued in its favor that it was not dangerous. This was not the case, however, as numbers of deaths have been reported as resulting from it. It has also been discarded in this country as of little value, although it is still used by many English surgeons.

We now come down to the consideration of the two great operative procedures on prostatotomy and prostatectomy, having thrown out all other methods.

During the last quarter of the preceding century, prostatotomy was an operation in which considerable interest was taken and many procedures were advocated by men who at the time were the leaders of the profession. Robertson performed prostatotomy within the rectum, the left forefinger being introduced as a guide, the knife was inserted along it and the prostate divided into two halves.

Harrison at the International Congress at Copenhagen, in 1887, advocated perineal urethrotomy, then dividing the prostatic bar on the floor of the gland, and stretching the prostatic urethra forcibly with his fingers or a sound. He was personally very much pleased with this method, and the literature of the time caused many to advocate it.

Mercier then devised a prostatome, for cutting through the median lobe, resembling the Bottini Incisor with a sharp male blade which he forcibly drew through the impediment in the floor of the prostatic urethra cutting a furrow in it.

Gouley adopted Mercier's procedure through a perineal incision. The instrument resembled somewhat that of Mercier's and was used to cut, or punch out, segments of the overgrowth. In this manner extensive portions of the gland were at times removed.

Norton modified Gouley's instrument working on the same lines.

Maissoneuve then advocated the Secateur. This was one of the most ingenious devices ever employed in genito-urinary work, although not as practical as his other instrument, the urethrotome. The shaft of this instrument had a curved beak at the end like a sound. The cutting blade was fastened in the centre of the convexity on a pivot and

lay concealed in the curve as far as the end of the instrument. After the beak had been caught behind the vesical base of the prostate, the blade was made to move in an arc of a circle, thus cutting through the gland in the floor of the prostatic urethra, and landing in the slot of the straight part of the shaft where it was again concealed, or else was again pushed forward to its former position when the instrument was withdrawn.

Some time in 1877 Bottini invented the galvano-caustic incisor, which was very similar to Mercier's instrument, differing from it principally in that the Bottini instrument cauterized whereas Mercier's simply cut. At that time the incisor was looked upon with disfavor, and it has been so considered until recently when it was modified by Freudenberg, of Berlin. This instrument, did, however, possess certain features of advantage which can now be clearly seen. In the first place the cauterizing knife is broader than a blade which traverses the gland tissue. In the second place it is not accompanied by as much hemorrhage. Again it burns the tissues for some distance on the sides, which when thrown off as a slough produces a gutter of some considerable width. Besides the cauterization has seared the vessels of the prostate, and thus has shut off the blood supply of the gland in a measure thereby causing it to atrophy.

The Bottini operation is then the sole surviving method of prostatotomy, which is used at the present day, and is one which we must consider among the so-called radical treatments of the hypertrophied gland, the other being prostatectomy. Prostatotomy is accordingly employed with a few modifications in the same manner by all surgeons who use it, and that is by the Bottini incisor.

Prostatectomy, on the other hand, varies in the numerous methods for extirpating the gland, and also in the detail of the technique. We will consider the various methods of prostatectomy later, and we will now speak briefly of the relative merits of the Bottini operation as compared with prostatectomy in general.

The advocates of each of these methods argue strongly in its favor. Followers of one procedure are wont to condemn the other operation. Supporters of prostatectomy contend that the Bottini operation is a blind one, and that the surgeon cannot see what he is doing, while the advocates of the Bottini operation say that enucleation is exact; the Bottini operation is a blind one, but so is prostatectomy, and in both cases we have to be governed by the sense of touch. In the Bottini operation we can fairly well determine the size of the gland by rectal and urethral examination, we then insert the instrument into the bladder, turn its beak downward and pull it toward us while the forefinger of the other hand is in the rectum. We can then feel just where the beak is. Many say that it sometimes catches in a diverticulum in the bladder, and that the end is not felt at the base of the gland by the finger in the rectum. We do notice at times that the end of the instrument is further back than the top of our finger which is pressing upon the border of the base of the gland through the rectum. This I would rather account for however, by the fact that the median lobe, or the intravesical tumor as it is better called, extends back into the bladder farther than the base of the gland does into the rectum; and I am convinced that I am correct in this surmise, for the suprapubic vesical prostatectomies which I have done, I have noticed a difference in the rectal and vesical bases of the prostate by bimanual palpation, the fingers of one hand being in the bladder and those of the other in the rectum.

With the instrument in place, and noting where it is by sense of touch of the rectal finger, and noting the distance which we are cutting, or cauterizing by the dial on the handle of the instrument, we can make an almost certain and definite cut for the number of centimeters required. Let us now look at prostatectomy for an instant.

It is a bloody and dangerous operation, much more so than the Bottini, and in my opinion it is as blind, if not blinder, for besides having to do with hemorrhage in the small hole that we are working in, the size of the hand hides the enucleating finger, and we can only work by the sense of touch and feeling. The prostatic gland which is so hard and indurated on examining it by the rectum

when the patient is not under an anesthetic, often presents an entirely different feel when muscular relaxation has taken place under an anesthetic, it then being softer and much more pliable. The finger especially in the perineal operation cannot be thrust between the capsule of the prostate and the gland without considerable digging and prostrate and the gland without considerable digging and forcibly prodding between the capsule and the gland. The enucleating process is not an accurate one, for no two prostates have lobes built on the same plan, nor are the curves and sizes of these lobes defined in the same way in all cases. Therefore we are pushing with the forefinger, overcoming obstructions, while working with its end when we can with difficulty bend the joint, pulling and pushing at times, while pressing from above and not feeling, I may say positively, the same certainty of what we are doing as when we are slowly drawing the Bottini blade through the hypertrophied gland. Taking it for granted that these are both blind operations we can say that successfully performed, the Bottini, while not so dangerous, does not produce such good results, and that the enucleation, while more dangerous, produces better results, if the patient survives, but we must never endanger our patient's life for the sake of choosing an operation considered more scientific. Let us consider what the indications are that will decide us upon which operation should be performed. They are as follows:—

The age of the patient.

The size and shape of his prostate.

The condition of his kidneys and bladder.

It may be said in a general way that very old men with not very large prostates, but causing considerable urethral impediment are cases for *Bottini* operation.

Younger men with large prostates as felt through the rectum, with good kidneys and bladder, for *Enucleation*.

Age is important, as the older the patient the lower his resisting power, and the more liable he is to death from shock and asthenia, therefore, in a very old man, if the prostate is of the right variety a *Bottini* operation should be performed, and cases of men over ninety years of age have been reported as having been operated upon by this method successfully. Old age, however, is not a contra-indication to prostatectomy, as men over seventy years old often have good kidneys, non-infected urine and a prostate which clearly indicates enucleation.

What, then, is the variety of prostate depending upon its size and shape which indicates one operation or the other? We may say that the very large prostates, such as have the feel of an apple or orange on rectal examinations, are favorable for enucleation, while the smaller ones, that is to say, those in which there is not much enlargement on rectal touch, but in which there is a distinct impediment in the prostatic urethra on introducing instruments together with a considerable quantity of residual urine, are the best for the *Bottini*.

One might ask if we can tell exactly how large a prostate is, as it often may not seem to be particularly large by the rectum, whereas the middle lobe projects to a marked degree into the bladder. In answer to such a question I would say that one can never say exactly what the size of the prostate is, or what its shape or its relation to the prostatic urethra and neck of the bladder any more than one can tell the difference of the two sides of the interior of the nose by feeling of the bridge and carefully passing the fingers over the cartilage externally; but the experienced rectal touch tells us a great deal, and when added to this we have a feeling of impediment in the posterior urethra as imparted to the sound, and are able to judge of the increased length of the canal by hooking the beak behind the middle lobe, and also noting the amount of residual urine present, we can form a fair idea of the prostate that we are dealing with. Besides this the cystoscope teaches us something of the contour of the base of the gland, though it does not, perhaps, show us as much of it as the mirror does of the nose when placed behind the soft palate. (The more I see of prostatic tumors, with projections, deviations, impediments, curves, etc., the more I think of nasal obstructions in cases in which we see a nose with a most perfect contour on the outside, and yet hypertrophies, atrophies, deviations of the septum, stenosis from obstructions, polyps and every conceivable condition of the interior).

Rectal examination is most important in telling us what to do, for if the gland seems to be too large per rectum, there is a considerable amount of residual urine and an im-

pediment to instrumentation at 7 inches or more in the urethra, and the urethra is lengthened, we can say that the hypertrophy of the lateral lobes certainly is considerable, but if the gland is small by rectum and the same conditions exist, we think that the impediment is principally median. Few practitioners have sufficient experience to outline the prostate correctly. This is brought out in teaching and consulting, and I can say truthfully that of the prostatic cases brought before me for a radical operation, not one-half of them are of the nature in which it is indicated. Whenever the prostate is much enlarged, and has the characteristic fibromyomatous feel enucleation should be performed, if the patient is not too old and the kidneys are in good condition.

Regarding the condition of the bladder and kidneys, it may be said that the bladder is least important, because it makes no difference how badly inflamed it may be, treatment will do much to benefit it by means of internal urinary antiseptics, and locally by irrigations through a catheter. An involved bladder does not count so much against an operation as kidney involvement does.

We have read in Guyon's works, and those of everyone who has studied Guyon, that one of the principal troubles in prostatics is an arterio-sclerosis of the vessels of the wall of the bladder, and that the stiffness is caused by interstitial changes in the bladder wall, and the interference with the blood supply, and that this prevents the bladder from emptying itself more than the impediment does. This may be true in a measure, but we now do not attach so much importance to the bladder, as we find that it can often empty itself almost entirely after prostatic operations, even if it has been considered hopeless before then, and sometimes even when years of catheter life have been passed.

Bad kidneys, whether medically or surgically diseased, are always contra-indications to surgical interference on the prostate, as in such cases any operation in the urinary tract is liable to be followed by a renal congestion, uremia and death. If, therefore, the kidneys are damaged in either a medical or surgical way, and an operation is demanded, a *Bottini* should be the one of choice. It must not be thought, however, that this operation is wholly without danger, as there often sets in after the operation a reaction which is most alarming.

The indications, then, for the two operations may be summed up briefly as follows: For a prostatectomy, a prostate of large size as felt per rectum, the larger the better, in a patient with healthy kidneys and urine.

A *Bottini* prostatectomy may, however, be performed in almost any case in which the instrument can enter the bladder, and may be of benefit even in marked cases of hypertrophy when an enucleation is clearly indicated, while in many cases of sclerosed prostates with a middle lobe impediment an enucleation could not possibly be accomplished. Cases have come to me where I have advised an enucleation to which the patient refused to submit, and a *Bottini* was performed. Some of these cases had complete retention, others partial, but they were all improved by the operation.

I have seen other cases in which there were considerable obstruction, large amounts of residual urine and all disagreeable symptoms in which an enucleation by the perineal route would have been absolutely impossible; by the suprapubic method only a piece could with difficulty be torn away, a piece consisting of dense tissue very different from large prostatic hypertrophy. *Bottini* operation should have been performed.

The Technique of the Bottini Operation:—The patient should lie on his back on the table. He can be operated on either with local anesthesia by cocaine or eucaine, or with general anesthesia, by ether, chloroform, or nitrous oxide. Personally I prefer general anesthesia by nitrous oxide gas. On the patient's left a fountain syringe should be hung, which contains the water for cooling the instrument, and on a stool near the patient's waist the battery should be placed. A soft rubber catheter lubricated with glycerine is passed into the bladder, the urine is drawn off, and the bladder is washed out and emptied, after which, before the catheter is withdrawn, if the operation is performed under a local anesthetic, a urethral hand syringe of a 4 per cent. solution of eucaine is injected into the posterior urethra and bladder, and as the catheter is being removed a syringe should be thrown into the urethra. From this moment the work should be done quickly and accurately,

and I have observed that the more quickly the operation is performed after the injection of the anesthetics into the bladder, in cases of local anesthesia, the less painful it is to the patient.

If cystoscopy is performed, the time required for it will usually be sufficient to allow the effect of the anesthetic to pass off before the actual operation is begun, and for this reason I think it advisable either to use the cystoscope at an earlier date, or to again inject a local anesthetic after the cystoscopy. Again cystoscopy is often more painful than the operation itself. It seems to me for this reason that it is advisable to omit the cystoscopy just before the operation, as advised by some, and consider it as having been performed previously when the patient was examined. Therefore, after the eucaïn has been introduced into a clean and empty urethra and bladder, the catheter should be quickly pushed back again and six ounces of water injected into the viscus, the catheter being quickly withdrawn and the incisor introduced. If it catches in the deep urethra, the pelvis should be elevated, which will allow it to enter if the handle is depressed and a slight upward push is given to the instrument. If it still catches the patient must be anesthetized. In four cases under eucaïne anesthesia I have failed to pass the instrument. I afterwards operated in three of these under nitrous oxide gas anesthesia, and introduced the instrument without difficulty. The obstruction is generally a spasm of the vesical sphincter.

After the instrument is in the bladder, its beak is turned downward, and then drawn forward until it catches against the base of the gland. The left forefinger is then introduced into the rectum to see if the instrument is in place. If it is, it should be held there, and the connection made with the battery, when a current of 45 amperes should be turned, drawing the knife through the gland from this point and burning a furrow in it. The current should then be shut off, the instrument turned to one side at right angles, and the current again opened, and an incision should be made through one of the lateral lobes, and then in a similar way through the other.

After the operation a catheter should be kept tied in for a few days, the patient should be given some urinary antiseptic and a milk diet, and should be instructed to drink large quantities of water daily. Ten grains of urotropin given three times a day is the best urinary antiseptic.

After the Bottini operation if the posterior urethra is much distorted by the prostatic hypertrophy it is sometimes advisable to perform a perineal urethrotomy for drainage. In a number of cases after a Bottini operation there is difficulty in introducing the catheter. This comes from a straight cut having been made from the middle of the vesical base of the prostate as far as the instrument will allow, and we have interfered somewhat with the tortuous channel by this direct cut. In these cases I should advocate an immediate perineal urethrotomy with the introduction of a perineal drainage tube of large size, 34 to 36 French. In a case operated upon under local anesthesia by a colleague the patient shrank back and allowed the beak of the instrument to slip forward over the convexity of the gland, thus cutting into the membranous urethra and perineum, a perineal urethrotomy was not performed at the time, necessitating a further operation for retention, followed by death from uremia and sepsis. This case would have been saved in all probability had a perineal operation been performed at the time. I have seen other cases where I am sure that had I performed a perineal section, my patients would have had a better result than by having refrained from doing so.

Prostatectomy is certainly the operation to which we should look forward for the radical treatment of prostatic hypertrophy in the future. Attempts have been made during a number of years to remove pieces of the gland through perineal incisions going into the urethra, and also after a suprapubic cystotomy by tearing away projecting impediments by the fingers and sharp instruments as the curette, etc. Within a few years, however, much advance has been made in this most important operation, until now we have operations by the suprapubic, the perineal, and the combined methods, as well as those by extensive dissection as Zuckerkandl's, Von Dittel's, Rydzier's and others.

It may be said that McGill is the father of advanced prostatic surgery, in that he made a beginning by removing small pieces in an unscientific way through the bladder after a suprapubic cystotomy, and grad-

ually began to formulate the operation until he succeeded in performing fairly satisfactory enucleations. His method was briefly as follows: He used the rectal bag, putting from 6 to 10 ounces in it. He then injected the bladder with from 10 to 20 ounces of water, leaving the catheter in the urethra as a guide until the bladder is opened. He opened the bladder suprapubically, attached it to the abdominal wall, and cut away pedunculated middle lobes if present with curved scissors. The sessile ones he cut in the same manner, helping the process by pulling the tissue with forceps. After removing these suprapubic obstructions he cut through the mucous membrane, over the projecting portion, inserted his fingers and began the process of enucleation, and at times aided himself with the forceps. After the gland was removed the bladder was then drained for a few days. In this way he removed pieces varying in size from a bean to a cricket ball, showing in these latter cases that he had evidently performed a complete enucleation.

Bellfield next took up the intravesical method of enucleating the gland, also accomplishing good results, and advocated the additional operation of perineal urethrotomy to facilitate drainage. Fuller has since then done a large number of prostatectomies, following in the line of McGill and Bellfield. The steps of his operation are as follows: After suprapubic cystotomy he cuts down (with scissors) through the tissues of the posterior wall of the neck of the bladder covering the gland, inserts the end of the finger into this incision, and digs out, or enucleates the gland with the finger, while pressure is made upward against the perineum by an assistant. In this way the bulk of the prostate can often be shelled out in three large pieces, while at other times it must be removed piecemeal. Enucleation cannot always be performed by this means, and frequently the operator has to be content with the removal of a piece forming the principal part of the barrier. A boutonniere operation is then performed and suprapubic and perineal drainage is established.

Personally I have been in the habit of performing prostatectomy by what I call the recto-vesical method, although no part of the operation proper is performed in the rectum, the fingers simply being inserted into it to exert direct counter-pressure and guide the operating finger, which is working through the bladder. The steps of the operation are briefly as follows: Suprapubic cystotomy is performed, after which retention sutures are passed through the bladder wall on each side of the incision. Careful rectovesical palpation is then made, two fingers of the left hand being in the rectum, while the right forefinger is in the bladder, and a visual examination is made by means of an electric light inserted into the bladder. A pair of scissors is inserted into the bladder, the point of the closed blades being pressed against its floor over the prostate in the median line, until the blades are felt depressing the prostate against the two fingers of the left hand in the rectum, which are in turn pressing upon the gland in the median line from below, showing exactly whether the scissors are in the right position or not. The blades of the scissors are opened, tearing through the bladder tissue, covering the gland in a line corresponding to the space between the two fingers in the rectum. The forefinger of the right hand is then inserted into this tear through the bladder, and gradually works its way between the capsule and the gland. The two fingers in the rectum feel the one in the bladder working its way between the capsule and the gland, and they start counterpressure while the enucleation is being performed. The finger tip under the capsule first sweeps to one side and pulls out one lateral lobe, then to the other side, and enucleates the other, and finally removes the middle lobe, or it first works its way backward under the base of the middle lobe, which is enucleated with a dissecting rotary movement, and then proceeds to enucleate the two lateral lobes. The gland having been removed there is always free hemorrhage, and very hot water should be injected for two or three minutes into the bladder suprapubically. I then pass a grooved sound, preferably a lithotomy guide, through the urethra into the bladder, and having brought the patient into the lithotomy position I rapidly cut through the membranous urethra and push a large perineal drainage tube into the bladder, which I fasten to one side of the perineal incision. The finishing steps of the operation are to put two catheters into the bladder suprapubically, with a gauze drain packed down beside them into the cavity made by the removal of the

prostate, fasten them into the skin of the bladder wall, and then sew the bladder wall up to the drain. I then close the abdominal wall, including fascia, muscle and skin as far as the drain. The floor of the prostatic urethra should be cut through from above downward before the perineal tube is left permanently in place to prevent the formation of a pocket, which would retard the cure.

The suprapubic incision enables the surgeon to see and feel the tumor distinctly from the bladder, as well as by the rectum. If a large middle lobe is found, called by some intra-vesical tumor, enucleation should be performed by the suprapubic method, but if we find that the enlargement is principally in the lateral lobes, it is better, perhaps, to remove it by the perineal route.

In Nicoll's method the suprapubic incision is the same, and the bladder is then attached to the skin by four stitches. The patient is brought into the lithotomy position, a sound is passed into the bladder, and a vertical incision is made down to the prostate. The assistant then puts his finger into the bladder, and presses the prostate up into the perineal wound. A second incision is then made at the lower extremity of the first at right angles to it, forming a T, and extending up between the rectum and the prostate. Two fingers of the left hand are then passed into the bladder

begins. The entire prostate is shelled out from within its sheath by a digital dissection. The mucous membrane of the bladder and prostatic urethra is stripped up from the parts to be removed, but is not opened. The lateral lobes are at first removed, after which the middle enlargement or tumors can be pressed down into the perineal wound and enucleated in the same manner. After the removal of the prostatic growth a perineal tube is passed into the bladder and a rubber drainage tube is inserted suprapubically. The suprapubic wound is closed above and below the drainage tube. The after-treatment consists in daily washing out of the bladder by injecting the fluid through the suprapubic tube. The upper tube is removed on the fourth day, and the lower tube on the seventh day, after which sounds are passed every five days until the perineal wound is closed.

In both these methods the bladder has to be opened in order to exert counter-pressure on the gland during the enucleation by the finger in the perineal opening, and as a suprapubic cystotomy is always a dangerous operation, more especially in prostatics where the system is below par, the bladder often not dilatable and the urine septic, efforts have been made to devise some means of making counter pressure without resorting to this measure. Syms,

Prostatic Hypertrophy.

suprapubically to press the prostate into the perineal incision. The capsule of the prostate is then cut through and pushed away on either side. The prostate is then enucleated with the finger of the right hand, assisted, perhaps, by a periosteum elevator, or a Volkmann spoon, without wounding the urethra or bladder. In the after-treatment Nicoll recommends passing a Coude catheter into the bladder, tying it in while he packs the perineum with gauze. He then takes out the stitches above the pubes and lets the bladder fall back again.

Alexander follows closely after Nicoll, improving and simplifying the details of the operation somewhat. His method is as follows: A suprapubic cystotomy is performed and retraction sutures are passed through the bladder wall. The patient is then put in the lithotomy position and a grooved staff is passed into the bladder through the urethra and an external perineal urethrotomy is performed through the membranous portion of the urethra to the apex of the prostate gland and its capsule incised. The fingers of the left hand are then passed into the bladder through the suprapubic wound, by means of which the prostate is pressed down into the perineum. The forefinger of the right hand is then introduced between the gland and the fibrous sheath over the prostate and the enucleation

of New York, has endeavored to obviate this necessity by a very ingenious device consisting of a thick rubber tube with a soft balloon on the end. This can be inserted with the balloon collapsed through the perineal opening into the bladder, after which it is inflated with water. It is then gently pulled down by an assistant, thus drawing down the base of the gland and steadying it while the operator enucleates through the perineal incision, the pressure being constantly kept up on the base of the prostate by pulling down the balloon.

Working on these lines, and feeling the necessity of a more complete and uniform pressure from above than could be obtained by a balloon in the bladder I have devised a method which I consider of great practical value in steadying the prostate and exerting counter-pressure during a perineal enucleation.

The steps of the operation are as follows:—The bladder should be washed out with boric acid solution through a catheter which is allowed to remain in situ, plugged after the bladder has been well distended for the purpose of avoiding perineal folds by pushing it well up above the pubes. The abdominal wall having been cut through above the symphysis the fingers of the left hand are thrust into the prevesical space where the prostate can be felt be-

tween the fingers. The plug is now removed from the catheter, and the fluid allowed to escape, thus permitting the bladder to collapse, after which the catheter is withdrawn. A staff is now introduced through the urethra, a perineal urethrotomy performed, the membranous urethra being cut through the apex of the prostate, at which point the prostatic capsule is incised, the forefinger of the right hand is inserted between the capsule and the gland and enucleation commences, counter-pressure being brought to bear upon the gland during enucleation by the index and middle fingers of the left hand in Retzius' space. Having enucleated the prostate by this means, I may say that the control of the gland by the fingers of the hand in Retzius' space is almost as complete as if they were in the bladder. After the lobes have been enucleated through the perineal opening a large perineal tube should be passed into the bladder and drainage should be kept up for three weeks or more. It is needless to say that the bladder is not opened in this operation.

Of the different methods of performing prostatectomy, that is, of removing the gland through the bladder supra-pubically, or through the perineum, or when the intravesical growths are present the bladder method is easier; and of the combined methods it is much the quickest, simplest and safest. Removing it by the perineal method with the fingers in the bladder to exert counterpressure is an operation which is not so simple, and in my opinion more dangerous, but I think time will prove that the operation just outlined will very much lessen the danger connected with perineal enucleation.

The After-Treatment:—An enema of a pint of hot saline solution at a temperature of 120°F. to be retained should immediately be given to the patient, together with a thirtieth of a grain of strychnine, and he should be put to bed with hot bottles at his feet. The shock in these cases is often great, and should be guarded against as much as possible. As soon as he comes out of the effects of the ether a little hot water, or bouillon, should be given, and from this time on the water should be pushed ad libitum. If the patient vomits the water, give more in a few minutes, and continue to force it. It is wonderful how much water can be taken in these cases, some patients taking between one and two gallons in the first twelve hours. This has the effect of flushing the kidneys and producing free diuresis. Any water is good for the purpose, although I am in the habit of prescribing some mild diuretic spring water.

The strychnine in one-thirtieth of a grain doses should be given every four hours hypodermically, and it is well to repeat the hot saline enema every four hours, alternating in this way something can be done for the patient every hour if the enemas and strychnine are alternated with the bouillon or water by the mouth, remembering that the water should be pushed to the maximum of tolerance.

It is well both before and after the operation to give a urinary antiseptic, preferably urotropin in ten-grain doses, three times a day. A diet of milk from two to three quarts a day is advisable. The bowels should be moved with some saline water, Apenta or Hunyadi on the second day.

In closing my remarks I should like to say that I consider the operation of prostatectomy still in its infancy, in the same position as was hysterectomy some years ago, and it behooves all surgeons interested in this line of work to try in every way to improve the technique of the operation now in vogue, and further to try other methods which will make the operation simpler than any yet that have been devised.

Protein Metabolism in the Aged.

G. KOVESI.

Kovesi directs attention to the fact that there have been only imperfect studies of metabolism in the aged, and that the statement that has been repeatedly made that metabolism in such subjects is reduced is based largely upon speculation. He reports a series of studies that he made in two subjects, 76 and 78 years old respectively, particularly determining the point to which the nutriment might be reduced with maintenance of a nitrogen balance. His general results were the discovery that the food demand in old age is decidedly reduced, and the daily demand is even lower than previous investigations have indicated.

It is about 20 calories per kilogram. The absorption of the proteids from the intestine was about normal. He was able to cause a nitrogen retention with the use of a very small amount of nitrogenous substances, because the demand for nitrogenous substances was so greatly reduced. The figures in this connection are very striking. With the use of 6.572 grams of nitrogen per day, 0.539 grams of which was excreted in the feces, he caused an average retention of 0.48 grams per day, the caloric value of the food at this time being 26 calories per kilo. Finally, he decides that there is decided reduction of the decomposition of nitrogenous substances in old age. All these disturbances are of quantitative nature. He believes that it should be recognized that senile involution occupies a special place in the question of the cachexias: carcinoma, tuberculosis, diabetes, etc., are associated with destruction of the body protein, and show qualitative changes of metabolism, while as stated, the contrary conditions are found in senile atrophy. This, he considers, indicates that the cause of involution cachexia is to be found in disturbed cell function. On the one hand there is a reduction in the demand of the cells for albumin, and on the other hand, the intracellular metabolism is of itself reduced and the general cell demand for energy is lowered. [D. L. E.]

Concerning Fatty Change in the Heart in Mankind. G. ROSENFELD.

Rosenfeld's article is chiefly a discussion of a recent one by Lindemann in which the latter author criticises Rosenfeld's previous statement that it would be better to speak of cell degeneration with deposit of fat in the cells, than of fatty degeneration. The chief points which Lindemann put forward against this statement were that he found the iodine continuing power of the fat in cases of degeneration much higher than with the normal fat of the heart or with infiltration fat. Lindemann decided that the degeneration fat was very different from the fat of fat depots, and that it was very different from the fat of the normal heart. He therefore decides that Rosenfeld's transportation theory plays no role in the cases of actual fatty heart. Rosenfeld criticises Lindemann's methods and figures. He particularly objects to his method of extraction, and insists that his own method of extraction with chloroform is much more complete and gives much more trustworthy results. He compares results obtained by the two methods. He then presents the results which he has obtained in examining a series of hearts showing conditions varying from normal to a considerable fatty change. The amount of fat in these hearts varied from about 15 per cent. in the normal cases to as high as 24 per cent., and in some there was marked so-called fatty degeneration. He found, however, that the iodine figures varied only between 67.8 and 75.7. He thinks that these figures are a strong indication that the fat found in the hearts in these cases was simple infiltration fat that had been deposited from the fat depots in the body. Another reason for thinking this was that he compared the fat on the right side of the heart with the fat on the left in two instances in which there was much more fatty change in the right side than in the left. The fat of the heart, while there was a much higher percentage of fat in the right side of the heart. He also insists that microscopically the main tissue picture is retained, and that in the early stages there is nothing more than an apparent deposit of small portions of fat. This gradually increases, and finally the fat deposit destroys the muscle substance by pressure. He insists finally that these results give further proof of his statement that fatty changes of the heart consists of a mere deposit of fat in the heart, and not of degeneration. [D. L. E.]

Otitis Caused by *Bacillus Pyocyaneus*.—Gelman (*Medycyna*, November, 1900), reports three cases of fibrinous inflammation of the ear caused primarily by the bacillus pyocyaneus. A pure culture of the organism was obtained in every case. No concomitant diphtheria was present. [A. R.]

The Plague Situation.—The report of the Plague Commission, appointed by the Secretary of the Treasury to investigate the situation in San Francisco, is very interesting reading, although beyond the one important and central fact that it demonstrates the existence of plague in that city, it throws no special or new light on the subject of plague in general. The energy with which the members of the Commission went to work, and the promptness with which they discovered what they were looking for, are noteworthy features. It is very evident that the disease was there and waiting for them, and the natural queries arise, How long had the plague been there; how many victims had it already claimed, and what had the local authorities in San Francisco been doing all the while? From all that we can gather from the report we should judge that the local authorities were not in command of the situation. The Commission had to undertake the investigation *de novo*. No report of previous cases apparently was given them; no evidence of scientific study before their arrival was forthcoming. It is true that the members of the Commission were well received and their work furthered by the local authorities; but these local authorities themselves seem either to have had no exact knowledge of the situation or else had, ostrich-like, closed their eyes to the real danger. To say that they had been deliberately concealing the truth is to make too serious a charge, but one cannot read this Commission's report and not feel that it is at least a strange fact that the situation depicted in it had been allowed to continue in San Francisco without recognition, while the rest of the country was being assured that there was no plague in that city.

Drs. Flexner, Novy, and Barker, who constituted the Commission, had no difficulty in finding six genuine cases of bubonic plague. The diagnosis in each case was confirmed by bacteriological tests. Guinea pigs were used for inoculation. The investigators worked under considerable disadvantage because of the prejudice of the Chinese and the filth of their surroundings, but they succeeded in demonstrating to the world the value of thorough-going, honest and scientific methods. Their report is an interest-

ing and valuable one, though its conclusions have already been known for some time.

The Protozoon of Cancer.—Dr. H. R. Gaylord, of the University of Buffalo, is not altogether fortunate in having been proclaimed in advance in the daily newspapers, as having demonstrated beyond dispute the parasitic origin of cancer. Such statements about scientific discoveries, when they filter beforehand through the newspapers, are more or less liable to be garbled, and to do both the author and his discovery some injustice by causing prejudice and prejudgment about his scientific work. We are now able to state authentically that Dr. Gaylord will publish early in May in the *American Journal of the Medical Sciences* in this city, a paper recording the results of his observations. He will give a full description of an organism, which belongs to the class of protozoa, and which he claims that he has demonstrated is the cause of cancer. In this paper he will report cases of the production of cancer in lower animals by inoculation with pure cultures of this germ. He will also present a summary of the length of life and of the gross lesions in 72 animals thus inoculated. He claims that this transfer of the disease to animals has been accomplished by inoculation with germs derived originally from human patients, and cultivated outside of the human body, and that the positive identification of the disease in these animals is scientific proof of the accuracy of his discovery. He also attempts to show the correlation of the findings of various investigators with the different phases of the living cultivated organism as he has observed it. He even calls attention to the relation of the organism of cancer to the protozoon of smallpox. This latter organism was discussed in these columns only recently. Eventually Dr. Gaylord, we are told, will give an analysis of the histological findings in the 72 inoculated animals, but this summary will not be contained in the article here referred to. It is too soon, of course, to attempt to subject Dr. Gaylord's paper to scientific criticism. We refer to it here merely as a matter of promised medical interest. It has already been heralded abroad so extensively that the scientific world will doubtless await the appearance

of the paper with interest. It is needless to say that it is entirely too early to prophesy what effect this discovery, if it be confirmed by competent observers, will have upon the therapeutics of cancer. In conclusion we may remind our readers that Dr. Gaylord claims that cancer is caused by a protozoon or animal parasite, not a bacterial or vegetable one. —

The Epidemic of Enteric Fever at New Haven.—Enteric fever and cholera are essentially water-borne diseases, and are largely conveyed to the human being by water used for drinking and cleansing purposes. It has been repeatedly and positively demonstrated that the specific germ of enteric fever, the bacillus of Eberth, is destroyed at a temperature of 100 degrees centigrade after 2 or 3 minutes. The lesson to be learned then in the prevention of the disease is to boil all water that is to be used for culinary or drinking purposes. It is a fact well established in the etiology of enteric fever that no case arises *de novo*; there must always be a previous case. If this be true, and there can scarcely be a doubt as to the correctness of this statement, then whenever a new case arises, the ordinary precautions regarding the disinfection of the excreta in a former case of enteric fever must have been neglected, facts that are taught and are familiar to the merest tyro in medicine. Epidemics of enteric fever are then due primarily to neglect by the medical men and perhaps largely also by the nurse in charge of such a fever case. It should be the duty of a physician in charge of a case of enteric fever, to see to it that his patient is not the cause of another case of the same affection. Care, and only care, can prevent the outbreak of this, at all times serious, affection. The authorities of a city cannot be held responsible if a careless medical man allows excreta of an enteric fever patient to contaminate the water supply of a large city. What can, however, be done by the "city fathers" is to instruct the citizens how to prevent the affection by boiling their drinking water, milk, etc., and not to eat uncooked vegetables and perhaps fruits. We fear that an epidemic, such as is at present raging in New Haven (where there are said to be over 500 cases of enteric fever, according to a report in the *Public Ledger*) is due to carelessness and neglect on the part of some of our medical brethren.

Suppurative Mastitis in the Newborn.—The mammary enlargement and inflammation which are not infrequently encountered in newborn children of both sexes are phenomena as yet not satisfactorily explained. Just why there should occur such glandular activity shortly after birth is not known, but that it may exist and even advance to actual suppuration, as in an instance recently reported by

Marvel (*Annals of Gyn. and Ped.*, April, 1901), is a well-recognized fact. As has been suggested, there may be some obscure relationship between the occurrence and certain metabolic changes taking place in the umbilical stump. It may be irritative in character from reflex excitation arising at this point. The theory of direct traumatism of the mammary gland is not proved and cannot be accepted. There is no substantial evidence in its support. It is true, however, that the suppurative form of the disease is traumatic in origin, and is due to the mal-directed efforts of nurses and midwives to squeeze out the offending discharge. The practical point that is suggested by the occurrence of infantile mammitis, is the necessity of careful handling of the gland, and the avoidance of any attempt at evacuation of the fluid. The absence of a thick pad of pectoral muscle renders the spontaneous rupture of the pus posteriorly into the pleural sac by no means improbable; hence emollient and absorbent applications should constitute the primary treatment with early incision, should pus develop. Above all, should vigorous manipulation of the inflamed organ be avoided in the primary stage of the disease.

A Wider Range for the Therapeutic Employment of Santonin.—Until recently santonin has been regarded as one of our most reliable anthelmintics, but its use in other conditions has not been recommended. However, attention has been called of late to the value of santonin in the treatment of epilepsy and the fulgurant pains of locomotor ataxia. The physiological action of santonin in large dose is chiefly upon the nervous system. Consciousness is disturbed, a sort of intoxication seizes the patient, accompanied by great weakness, tremors, sweating, coldness of the surface, and vomiting. There also follows a slowing of the pulse with enfeebled respiration. Mydriasis occurs with a frequent onset of convulsions. Between the convulsions there is sometimes paralysis of respiration which usually causes death. The most characteristic action of the drug is upon the vision. At first everything appears colored blue, and afterwards yellow or greenish-yellow. The blue appearance is very transitory, but the yellow vision (chromatopsia) lasts much longer. Following this, if very large doses have been taken, total blindness, sometimes lasting a week, occurs. It is said that this alteration of the vision is due to stimulation of, and later paralysis of, those fibers of the retina by which blue light is perceived. Dr. C. Negro, of Turin, observing particularly the action of santonin upon the retina reasoned that it should be capable of influencing general changes of nervous sensibility. This supposition was fully verified in a patient with tabes, to whom Dr. Negro administered santonin to combat the

painful crises. His results were most satisfactory, and since this time he has treated a number of similar cases always with favorable results.

He administers *santonin* in doses of 15 centigrammes a day, taken at intervals of three or four hours. These doses have generally been found sufficient to completely abolish the fulgurous pains. Lydston has used *santonin* in the treatment of a number of cases of epilepsy, and he believes that the action of the drug is much more favorable than the bromide-treatment. Lydston begins by administering 2 grains of *santonin* gradually increased, as tolerated, until as much as 15 grains, taken 3 or 4 times a day, is given. He has usually found this amount to be well borne. The advocacy of another remedy in addition to the host of those recommended in the conditions we have named, will no doubt be regarded by very many physicians as of doubtful value. But the results which have been attained from the employment of *santonin* seem to justify an extended trial on the part of the profession so that its precise value may be accurately determined.

The Latest on Women Doctors.—A wise man once said that you cannot indict a whole race. He might have added with equal pertinence that you cannot indict the whole female sex. We do not suppose for a moment that Dr. Victor C. Vaughan, of Ann Arbor, Mich., intended in his recent pronouncement against women doctors to indict the whole sex. He evidently had in mind only that portion of the sex that studies medicine. This small minority will doubtless bear him in mind and feel duly grateful to him. In a recent address Dr. Vaughan proclaimed that women were often successful in the class-room by reason of their mental qualities, but were not adapted to practise medicine because of a kind of lack of resourcefulness and self-reliance. It seems to us that we have somewhere heard this criticism before, but still, for the time being, we will let Dr. Vaughan have entire credit for it. The doctors in question will doubtless think that what it lacks in originality it makes up in erroneousness. The many women who are successfully practising medicine in the United States to-day are perhaps not all of the strenuous kind, and they may have self-reserve enough not to rush into print to assail Dr. Vaughan; but keen observers of the facts in some of our large cities must know that some of these women are resourceful and masterful enough to command a gratifying success. We do not believe that the mental traits of the two sexes can be quite so sharply differentiated as Dr. Victor C. Vaughan imagines they can be. Scientific training tends to eliminate some of the mere sex factors in mind—factors which after all are largely conventional and

the results of social evolution. The wide swoop of such an indiscriminating pen as Dr. Vaughan rather rashly flourishes fails to include too many minor problems in the question. We are convinced that these problems will not be settled by purely masculine criticism.

A School for Backward Children.—The Public Education Association of Philadelphia has undertaken a most praiseworthy task in conducting a public school in this city for "backward children." This term "backward" covers a variety of defects, and this fact is fortunately clearly seen by the Committee. It indicates that many of these children merely present need for *special* training by reason of some one special physical or mental defect. Thus, children who are deaf but not mentally deficient, or children who stammer or who have other speech defects, are instances of pupils who require special methods of instruction. One of the grave defects of the public school systems in this country is their hard-and-fast mechanical workmanship. The individual needs of the scholar receive too little attention. In the case of a child who is in any way handicapped by physical or mental defect, this rigid and impersonal system is fatal. Hence, as the Committee says, ungraded rooms are needed for many kinds of pupils who are "misfits" in the regular grades. As for children who are congenitally deficient in mental faculty, the real hope of helping them lies in manual training. Such children are taught wood-work, card-board work, clay-modeling, chalk-work, basket-weaving, painting, and sewing. We have just received the annual report of the Committee, from its secretary, Miss Dora Keen, and commend it for full details to all persons interested in this benevolent work.

Christian Scientists Barred.—We expressed the opinion some weeks ago in these columns that the proper way to do with the Christian Scientists was to require them to obtain a license to practise medicine after passing an examination, just as is demanded of all other candidates. No amount of criticism and denunciation will exterminate this sect. Anything that savors of persecution is to be feared, for such fanatics always thrive on persecution. They court it, and would even gladly go to jail and liken themselves to St. Paul in chains. There are plenty of such people in the world, even outside the ranks of Christian Scientists; men who pose as prophets and reformers. They are shrewd enough to know that a certain kind of popular sympathy is easily aroused for a martyr who appears to suffer for conscience's sake. When, however, they are required to meet a law that applies equally to all, they are forced to show their hand, and at the same

time are debarred from playing the role of the persecuted. The recent opinion of Judge Lumpkin, of the Superior Court of Georgia, is exactly in accord both with law and with reason. The Judge denied the application for a charter for "The Atlanta Institute of Christian Science," basing his decision on the opinion that Christian Science is a form of medical practice, and that the practice of medicine in Georgia, according to the law of the State, can only be pursued by persons who are regularly graduated from medical schools. Judge Lumpkin's decision seems to debar these people from legal recognition in the State of Georgia, and if they persist in their practices they can be treated as any other law-breakers.

The Barbers and the Surgeons.—It must be difficult for most readers in this country to realize that in England the surgeons still hobnob with the barbers, and that members of the two "professions" still regard each other as fellow-craftsmen. This odd relationship has just been illustrated by the address delivered by Sir William MacCormac on the occasion of his receiving the Honorary Freedom and Livery of the Barbers' Company in London. This fellowship had its origin in the remote past, at a time when the barbers were the only recognized surgeons, or "barber-chirurgeons" of the country. A relic of their surgical prerogatives still lingers in their practice of leeching, bleeding and cupping, even in this country, and their sign with its red stripes is said to indicate their gory occupation. In England the tendency is to adhere to tradition and to hold on to old ways and customs, and so it came about recently that the barber's guild had for its chief guest a distinguished surgeon whose career and attainments do not at all suggest anything tonsorial.

But the modern Company of Barbers, we suppose, must not be taken too seriously. It seems to be celebrated for its antiquity and for its old silver plate rather than for the art of hairdressing. We doubt whether any of its members have to make their living by cutting hair and shaving. Sir William MacCormac in his address tells us that the Guild of Barbers in London is of such ancient foundation that its earliest records cannot be traced. It dates from the Thirteenth Century. At first it had even a religious character, as the barbers used to assist the monks to perform operations. This must have been in still earlier days, for the edict of Tours, in 1163, forbade the priests to shed blood. In 1462 a charter was obtained, and in 1540 the surgeons (an insignificant body) became merged in the Barber's Company. From this time, for two hundred years, the surgical practice and teaching of England were in the hands of this

Guild. Its members were surgeons to the King and they were content to bear the humble title of "barber-chirurgeon." In fact, they rejoiced, as their descendants appear to rejoice to-day, in what to outsiders seems to have been a somewhat plebeian origin. The surgeons were not formally separated from the barbers until 1745, when they formed the Company of Surgeons, and this company became eventually, in 1800, the College of Surgeons. In France things were much the same, and the celebrated Ambrose Paré, who was surgeon to five successive kings of France, was a mere barber surgeon. The practice of surgery was held in low esteem as compared with the practice of physic, and, as Sir William MacCormac says, it did not advance much from that time until the evolution of antiseptic surgery toward the end of the Nineteenth Century.

A Medical View of the Chinese Boxers.—It was hardly to be supposed that the opportunity of writing about the psychology of the Chinese Boxers would be allowed to pass. This age in which we live is the psychological age. Everything from a pastime to a crime must be subjected to a psychological analysis. This sometimes looks like psychology gone mad. In fact we might almost call it the psychiatry of criticism. It is natural, however, that a French physician should be among the first to call attention to the hysterical phases of the recent insurrection in China. M. Matignon tells us that he was impressed long ago with the fact that hysteria is very common in China, and in the spring of 1900 he undertook to investigate the subject. He examined more than 300 subjects and proposed to extend his anthropological researches to three or four thousand cases, when the catastrophe at Peking put a stop to his studies and caused him the loss of his notes. He, however, has recently given his impressions, which are that nervous diseases, contrary to the general opinion, are extremely common among the Celestials. He says that hysteria especially exists, and that the Boxer uprising has thrown new light upon this affection as it is seen in China. He thinks that the Chinese mind is very open to suggestion. The Chinaman believes more as he understands less, and that which he does not understand at all he has absolute faith in. Last year this natural suggestibility was raised to the paroxysmal point. The whole Chinese Kingdom was in a state of anxiety which M. Matignon likens to the state which existed in Europe in the year 1000 at the prospect of the second Advent. The year 1900 was to have an intercalary month, and this was a grave omen which caused an exaggerated suggestibility in the Chinese mind. M. Matignon evidently thinks that the Boxer uprising was a sort of pandemic frenzy, not un-

like, we suppose, some of the popular manias which swept over Europe during the Middle Ages.

We are not disposed to criticise M. Matignon's view adversely, although he may have forced his conclusions rather too far. We would remind those who are interested in the subject that Dr. Nevius, an American missionary in China for forty years, wrote a curious book a few years ago on demon possession as he had observed it in China. Dr. Nevius unfortunately was entirely without scientific knowledge and critical acumen, and doubtless misinterpreted the many curious psychological phenomena which he had observed in the Chinese during his long sojourn among them. He was evidently also prejudiced by his environment and took the extremely superstitious and theological view of these mental traits. He believed in a veritable demon possession, although what he observed was evidently an outbreak of wide-spread hypnotic manifestations in the Chinese peasantry. If he had had the knowledge and literary skill of M. Matignon, without the superstition which disfigured his book, he could have made a most interesting contribution to the science of comparative anthropology. He entirely ignored the power of hypnotic suggestion, especially as it occurs under the influence of religious excitement. In fact, the good missionary had lived so long in China that he seemed never to have heard of such a thing. The consequence was that instead of his book being a contribution to science, it was only a detriment to the cause of religion. We have no doubt that the Chinese have the mental characteristics that are common to the whole human race, and that in such a furious outbreak as that which occurred last year under the influence of religious excitement and racial animosity they may have exhibited most interesting symptoms of mental perversion. We are indebted to the *Literary Digest* for an interesting reference to M. Matignon's article.

The Decline of Population in France.—We see a great deal written here and there about the decadence of France, and especially about the decline of her population. Some of the facts and figures seem to us to be altogether misinterpreted. In the first place, the assumption that every country on the face of the earth must show a decennial increase of population, or else be judged decadent, is only an assumption. There comes a time in the history of every country, (and even of different parts of a country), when what is called the "saturation" point is reached. At this point the country can support no more people. To have reached this point is not necessarily a sign of stagnation; quite the reverse, it may be an evidence of a very high state of civiliza-

tion. France has apparently about reached this point. For that matter, there are some localities, or even States, in our own country which have almost if not quite reached the same point. By the end of another half-century, such phenomena will have become more common in the United States. At the present rate of increase, in fact, it would take but a comparatively short time (as historical time is measured) for the whole United States to be densely overpopulated. What will be true of America, has been true for some time of part of Europe; and France, which is the centre and one of the most densely populated of the European States, is simply in the position in which some of our own American States will probably be long before all adult persons now living shall have died.

A recent writer calls attention to the fact that the more civilized a nation becomes the denser population it can support. In the Stone age France could support but a few thousands; in her Golden age she supports many millions. Another writer casts a reproach upon France because she does not increase so rapidly as Russia; but Russia has a vast territory, some of it almost unpeopled. Such a comparison is quite absurd.

It is well to remember that as the "saturation" point is attained there are natural checks on the increase of population. Nature looks after her own in this respect. A slight relief from over-population, even by a reduction in the birth-rate and an increase of emigration, is not always a bad thing, as history has shown. It is like putting some of the persons out of an overcrowded room, and letting no others come in. From a hygienic and medical standpoint over-population is much to be feared. Therefore, instead of deploring the lot of France, it may be well to inquire deeper and see whether things are really going to destruction with her.

On the Agglutinating Power of Some Serums in Relation to the Red Blood corpuscles of Man.—Jean Camus and Pagniez. (*Gaz. Heb. de Med. et de Chirur.*, March 7, 1901, 18 me. Annee, No. 19).—At a meeting of the *Societe de Biologie* held March 2, 1901, Camus and Pagniez made a report on the **agglutinating power of some human serums in relation to the red corpuscles in man.** They have found that, in the pathological state, human serum may agglutinate the red blood corpuscles of another man. Their studies have included 35 specimens of human serum, both normal and abnormal. Normal serums do not give agglutination so far as the studies have gone. Among the pathological serums a large number were endowed with manifest agglutinating properties. They agglutinated the red blood corpuscles of normal man but had no action upon these cells taken from other men suffering from disease. The active serums came particularly from patients suffering from anemia and cachexia, the majority of whom were tuberculous. The red cells of a patient furnishing a very agglutinating serum may be completely refractory to agglutination by other serums. As in the case of animal serums, heating to 58° C. or 60° C. diminishes without destroying the agglutinating property. [J. M. S.]

Correspondence.

THE TREATMENT OF PNEUMONIA WITH SALINE INFUSIONS.

By CLEMENT A. PENROSE, M. D.,
of Baltimore, Md.

To the Editors of "The Philadelphia Medical Journal."

Dear Sirs:—As my paper on salt infusions in pneumonia which received very favorable criticism over two years ago, when first presented before a body of eminent men (Johns Hopkins Hospital Society, January 23d, 1899), was made a leading editorial in the British Medical Journal shortly after, and led to some experiments being made in England, I cannot believe that it lacks a theoretical basis, and fear that Dr. D. E. Keefe's criticism comes, alas, too late to warn his brothers against the method which many are using, and I believe will continue to use.

I felt that Dr. Keefe's ideas on saline infusions were evidently preconceived, and that he had ignored the recent literature on the same when he states by way of a preface to his article, that "he is opposed to their use in cases of collapse after surgical operations unless from hemorrhage." I hope such a statement is based on experiment and not on theory alone. Recent work by some of our best surgeons has demonstrated the great utility of saline infusions in septic cases, after operations on the intestines, appendix, abdominal organs, and so forth, in which little or no blood is lost, which now fortunately is the case in most operations.

The question of edema of the lungs is a very ticklish problem, both regarding its physiology and pathology, and I take exception to Dr. Keefe's positive deductions. According to the best authorities, edema of the lungs is almost always secondary to heart failure, primary edema being a rare occurrence. Possler quite recently (*Munch. Med. Wochens.*, No. 8, February 19, 1901), believes he has demonstrated by inoculation of rabbits that the heart failure or sudden collapse in pneumonia is not due to cardiac weakness from overwork and so forth, but to paralysis of the vasomotor centres in the medulla from which it might be concluded that the small additional work given to the heart is more than compensated for by the relief, through the salt infusions, to the septic condition.

Dr. Keefe says: "Saline infusions fail in pneumonia because in the inflamed lung there is almost complete stasis by reason of the exudate outside and the clotting within the vessels." My own pathological studies have shown me that throughout all stages of pneumonia in spite of the pressure on the walls of the air spaces in the diseased portions of the lungs, the blood vessels for the most part remained pervious during life, and clotting or thrombosis takes place only in the very smallest vessels and capillaries, and to little extent in the great majority of cases. If salt infusion increases the circulation through the lungs, affected areas and otherwise, it may tend to prevent stasis. I am, however, inclined, owing to the complex nature of this subject, to lay stress on clinical experience rather than any theoretical deductions. Further observation in my own practice and that of others has made me feel that there is little danger of pulmonary edema, especially if infusions are given in parts remote from the lungs, i. e., thighs, abdominal muscles, and so forth. A few autopsies on patients infused under the breasts after surgical operations have shown in some instances blebs on the parietal pleurae. The mere weight of the fluid given subcutaneously, might be a slight impediment to respiration before absorption, which is usually rapid, has taken place.

As the importance of watching the pulmonic second sound in pneumonia, and bleeding when this becomes too accentuated or murmurish, has been emphasized by one of the greatest authorities on hearts in our profession, I must regret that it seems a useless signal to Dr. Keefe. The

statement that free oxygen in the blood is of no consequence is a questionable one, and any effect from diluting the haemoglobin may well be counterbalanced by the increased opportunity given to the blood of getting oxygen through the stimulation to the respirations which in all my cases became easier and deeper, and so continued.

From Dr. Keefe's paper, I judge he lays little stress on general toxemia. He speaks of toxins in the lungs, and says, "They are here mostly situated." Are toxins mostly situated in the throat in diphtheria? We trust the Doctor is not confusing the bacteria themselves with their products. When a patient after several days of muttering delirium becomes conscious a few hours after a saline infusion, I certainly have every reason to believe that great elimination or dilution, if you please, of toxins has taken place. More stress is laid every day on the agency of the kidney and spleen in removing toxins from the blood through the urine and sweat, and nothing increases these more with less depression than saline infusions, as is demonstrated daily in uremia, eclampsia, etc.

In conclusion, it may be stated most emphatically that I am prepared, in the light of further investigation, to stand by the facts laid down in my original article. My cases were presented most accurately; in fact, were well known to many before whom they were reported. My results were fairly given to the medical profession, and endorsed by prominent physicians. That many fine physiological points were involved was most apparent, and any theories advanced to explain the undoubted facts were presented with the hope of discussion by the physiologists of our Society. I cannot see that Dr. Keefe has justified his criticism.

The idea of employing a diluted anti-pneumotoxin serum, although not original with Dr. Keefe, is a good one, and some further work on this matter may appear in the future.

PAROTITIS COMPLICATING PNEUMONIA. WITH THE
REPORT OF A CASE.

BY GEORGE WILLIAM NORRIS, A. B., M. D.
of Philadelphia.

To the Editor of "The Philadelphia Medical Journal."

The following case was seen in the service of Dr. J. C. Wilson at the Pennsylvania Hospital during February of this year.

J. S. aet. 58, was admitted suffering from a croupous pneumonia of the right side. He was desperately ill and his life was almost despaired of. Recovery however followed, the disease terminating by crisis on the 9th day. Three days after this time the patient began to complain of pain at the angle of the left lower jaw. This region, which was at the time noticed to be swollen, increased rapidly in size, and became intensely swollen and tender, the overlying skin being tense, red and angry looking. Six days later distinct fluctuation developed. Three days after the swelling had first been noticed on the left side, the right began to be involved and soon presented, though to a less marked degree, the appearance of the left. The glands were incised by Dr. R. H. Harte, and a large quantity of pus evacuated, which gave a pure culture of the staphylococcus pyogenes aureus. Recovery followed.

Parotitis has been considered a rare complication of pneumonia, and probably is so, although quite a number of cases have been reported within the last few years. Out of a series of 500 cases of the latter disease recently tabulated by the author from the records of the Pennsylvania Hospital,* the condition was met with only once. From a study of the literature I have been able to collect in all eighteen cases, (present case included), from the study

of which the following facts have been gleaned. The complication is met with in all ages, more commonly in males. It usually appears with the defervescence whether by crisis or by lysis. The side involved bears no constant relation to the seat of pulmonary lesion. Both parotid glands were involved in four out of the eighteen cases, the involvement being successive. Incision and evacuation of pus were necessitated in five cases. One evacuated spontaneously. The pus was examined bacteriologically in only three instances. In one case pneumococci were present. The staphylococcus pyogenes aureus was found in this case, as well as in the two remaining ones. Death resulted in three cases, all of which were complicated, one by cystitis, one by endocarditis, one by endocarditis and empyema. In none of these cases of parotid bubo was there apparently any reason to suspect that the glandular enlargement was due to the specific infection of mumps. None of the cases evinced any tendency to contagiousness, there being no involvement of the testes or mammae, and suppuration occurred frequently.

The channel of infection was probably through Stensen's duct; although it is possible that a blood metastasis occurred in Scott's case in which pneumococci were found. Parotid bubo is broadly speaking an uncommon condition, and why an attack of croupous pneumonia should predispose to infection of the gland through its duct does not seem evident.

The presence of pus as indicated by fluctuation, being in this region usually hard to determine owing to the density of the parotid fascia, incision should be made as soon as a presumptive diagnosis of suppuration has been established. The well known dangers of pus in this region—i. e. paralysis of the facial nerve, infection of the auditory meatus, mandibular articulation, or even of the brain or the formation of a retro-pharyngeal abscess, far outweighing all other considerations.

The 17 cases are reported by the following authors:
 Carlow, (2 cases), Glasgow Medical Journal, July, '95.
 Osler, Univ. Med. Mag., Jan., '94.
 Hawthorne, Glasgow Med. Jour., July, '95.
 Talley & Gittings, "Phila. Med. Jour.," Mar. 28, 1900.

THE BRAINS OF TWO MORE CELEBRITIES.

BY E. A. SPITZKA,

of New York.

To the Editor of "The Philadelphia Medical Journal."

Dear Sir:—Subsequent to the completion of my paper on the brains of the Doctors Seguin, father and son, I obtained the reports of two recent examinations, those of Madame Sonya Kovalewska, the celebrated mathematician, (G. Retzius: *Biologische Untersuchungen*, Neue Folge, IX. 1900, pp. 1-16.) and of Professor Carlo Giacomini, (*Giornale della R. Accademia di Torino*, August 1900, pp. 737-808). The brain of the latter adds a noteworthy item to the chapter of coincidences since Giacomini's brain exhibited a striking anomaly which he himself was the first

to describe, namely: *two central fissures*, and therefore a so-called *gyrus Rolandicus*, upon the right side.

The brain of Sonya Kovalewska was not weighed until after four year's immersion in alcohol, the weight being then 1108 grams. Retzius calculated the original weight to have been about 1385 grams.

A WORD FOR THE CIGARETTE.

BY WILLIAM J. ROBINSON, Ph. G., M. D.

of New York.

To the Editor of "The Philadelphia Medical Journal"

A few words apropos of your editorial, *The Crusade Against Cigarettes*, in a recent number of the "Journal." The writer is not and has not been a smoker. He smoked but one cigarette in his life, and that was when he was seven years old; and that one made him so deadly sick that he never after had any desire to court the fragrant weed. If I make bold enough to speak in favor of the cigarette, I cannot well be charged with partiality or partisanship. That smoking by minors or children is injurious I admit. That smoking is or may be injurious to adults suffering with any buccal, lingual, pharyngeal, laryngeal, tracheal, bronchial or pulmonary troubles, I admit. But that cigarette smoking is capable of doing the damage ascribed to it by some sensational newspapers is extremely questionable; and that cigarettes are in any way more injurious than cigars is positively false. That smoked to excess both cigarettes and cigars may cause serious injury, is probably true. But no article or method should ever be condemned for its abuse or misuse. Tobacco is a sedative and all sedatives are dangerous when used to excess, but when used occasionally and in moderation cigarette smoking may prove distinctly beneficial. The writer has seen more than one case in which a cigarette allayed nervousness and irritability and produced a distinctly soothing effect; especially so in women of a delicate nervous constitution. In one case I prescribed it as a remedial measure, and it gave better results than the bromides or valerian. I hope I shall not be misinterpreted as advocating that American women should follow in the footsteps of European aristocracy and take up cigarette smoking, but I do say that if the poor cigarette is to be condemned and ostracised it should be on scientific grounds after a thorough and sober consideration of all the facts and evidence. To call smoking immoral and condemn it on that ground—well, it shows that some people have a very, very queer notion of what is moral and immoral.

The Effect of Carbonic Acid Baths on Healthy and Diseased Circulation.—Kowalsky (*Przegląd lekarski*, Nov.-Dec., 1900), found that in healthy persons baths of 30-33° C. diminish the activity of the heart and raise the blood pressure, the pulse becoming hard and tense. A temperature of 36-39° C. increases the heart's action, lowers the blood-pressure and renders the pulse soft. In diseased conditions of the heart these effects are greatly intensified, almost doubled. Baths of a temperature lower than 34° C. are indicated in all cases of cardiac insufficiency dependent either on valvular disease or degeneration of the heart-muscle. They are contraindicated in all cases of circulatory disturbances accompanied by increased blood-pressure and also in interstitial nephritis. In these conditions the temperature should be above 34° C. Cold baths (below 34° C.) also act on respiration and the excretion of urine, the former being rendered less frequent and deeper, the latter being increased. [A. R.]

Reviews.

Human Placentation. An Account of the Changes in the Uterine Mucosa and in the Attached Fetal Structures, During Pregnancy. By J. CLARENCE WEBSTER, B. A., M. D. (Edin.), F. R. C. P. E., F. R. S. E. Professor of Obstetrics and Gynecology in Rush Medical College (affiliated with the University of Chicago); Fellow of the American and Chicago Gynecological Societies and of the Edinburgh Obstetrical Society; Corresponding Member of the Royal Academy of Medicine, Palermo, Italy, and of the Italian Obstetrical and Gynecological Society; Late Lecturer on Gynecology, McGill University, Montreal; Formerly First Assistant in the Department of Midwifery and Diseases of Women, University of Edinburgh, Scotland. With 233 Illustrations. W. T. Keener & Co., Chicago, 1901.

Dr. Webster's book on the development of the human placenta is based upon eleven years' work, during which time he has examined the uterus in the second, third, fourth, fifth, sixth, seventh, eighth, and ninth months of pregnancy, in the three stages of labor and at various times during the puerperium. He has also studied a number of complete abortions in the early weeks of pregnancy, and has examined the pregnant uterus in various stages from the mouse, the rat, the rabbit, the guinea pig, the pig, the sheep and the cow.

This list of tissues examined is extensive; but for the condition of the uterus during the first few days of pregnancy the author has been obliged to make extensive use of the monograph of H. Peters on the *Embedding of the Human Ovum and the Earliest Known Stage of Human Placentation*, which appeared in 1899. This is a description of probably the youngest human blastodermic vesicle known; it has thrown light on many points in the evolution of the placenta that were formerly most hazy and has caused us to make radical changes in our ideas concerning this organ.

The first chapter is devoted to a consideration of the structure of the normal uterine mucous membrane in the adult nullipara. The author states that the lining epithelium consists of ciliated, columnar cells, and in this he agrees with the statements made in the text-books. The cilia of this epithelium are extremely difficult to demonstrate, however, and in the photomicrograph of the mucosa of the normal uterus these cilia are not shown.

The second chapter treats of the formation of the decidua vera. The author believes that the nature of the change from the nonpregnant condition is one of marked hypertrophy of the preexisting cellular elements in the interglandular tissue of the normal mucosa, and he has entirely abandoned, and for the best reasons, the older view that the decidual cells are developed from leukocytes or from the glandular or surface epithelium of the mucosa. In normal cases, the author finds that hemorrhage occurs only to a slight extent.

The third chapter treats of the formation of the decidua reflexa; decidua capsularis or circumflexa being the preferable term for this portion of the decidua. Here, again, recent researches, including those of the author, require that we abandon the old idea that the hypertrophied mucous membrane folds around the blastodermic vesicle, and we have now the more rational view that the ovum erodes its way into the substance of the mucosa and thus the capsularis is produced. We have always been taught and have in turn taught that the capsularis in the later months of gestation blends with the vera to form a single layer. The author confirms the views of Minot and E. Fraenkel that the capsularis is destroyed and that the chorion leve lies against the decidua vera. The capsularis, according to this interpretation of specimens, is removed by a process of coagulation necrosis; no evidence of fatty degeneration having been found.

Chapter four is devoted to a consideration of the changes in the decidua serotina, which in the newer nomenclature is known by the more comprehensive designation decidua placentalis. In his investigations, Webster has reached the same conclusion that has been reached by Peters and others, that the syncytium is not produced from the

epithelium of the uterine mucosa, but from the fetal ectoderm which covers the chorion. These studies show, further, that there is no evidence in support of the view that the lumina of the glands help to form the intervillous spaces of the placenta. The progressive changes in the decidua are not mechanical; the epithelium on the surface and in the glands is shed, probably on account of the lack of nutrition due to the occlusion of the lymphatics. The degeneration in the interglandular tissue is principally of the nature of coagulation necrosis, which gives rise to a progressive hyaline or fibrinous change.

The fifth chapter treats of the early relations between the ovum and the decidua. The most important part of this chapter relates to the method of establishment of communication between the maternal blood sinuses and the intervillous spaces of the chorion. We have always been taught that the maternal capillaries rupture. The author, following Peters, is of the opinion, however, that the trophoblastic hypertrophy of the chorionic ectoderm absorbs the endothelial walls of the maternal vessels by phagocytic action. He points out, and with reason, that the capillaries in the decidua vera are dilated as well as those in the decidua placentalis and asks the pertinent question: If the latter capillaries rupture spontaneously, why not the former?

The chorion and the amnion are discussed in chapters six and seven, and in chapter eight the plane of separation of the ovum is discussed. The author finds that in normal cases the separation of the placenta and the membranes takes place through the compact layer of the decidua, and not through the spongy layer, as formerly taught. If these observations are confirmed, we shall again be obliged to revolutionize our teaching.

In chapter nine the author describes the shed placenta and in the tenth chapter the phylogeny of that organ is discussed.

In all, the book is an important and thorough contribution to the subject of development of the placenta, and throws light on many theoretic points that have long been open to serious doubt, but that have been accepted on account of the authority of those responsible for the theories.

An extensive bibliography is appended, and there are two hundred and sixteen reproductions of photomicrographs. The latter, we think, are not as clear as reproductions of careful drawings would have been. [J. M. S.]

3500 Questions on Medical Subjects for Self-Examination.

With the Proper References to Standard Works in which the Correct Replies Will be Found. Third Edition, Enlarged. With Questions of the State Examining Boards of New York, Pennsylvania and Illinois. Philadelphia: P. Blakiston's Son & Co., 1901. Price, 10 Cents.

Self-examination for medical students is a thick book in paper cover, published by the firm of Blakiston's Sons & Co., the pages of which measure $3\frac{1}{2}$ by 4 inches. The book purports to be compiled by a medical man and a writer of experience. It is said that by its help the student can successfully quiz himself on all the important branches or review any one subject in which he feels himself to be particularly deficient. In point of fact the book is an advertising scheme for the publications of the Blakiston firm, since after each of the questions, of which there are 3500, is a set of figures, such as 9-27. Of these figures 9 refers to a quiz-compend on surgery, published by Blakiston, and 27 refers to the page in the quiz-compend on which the answer will be found. All of the "standard works in which the correct replies to these questions will be found" are quiz-compends, with the exception of Gould's Medical Dictionary and Morris's Anatomy. The entire book is founded on an erroneous conception of the value of the quiz system and of methods of study. How can any one imagine that by learning answers to 3,500 or 35,000 questions, a student can fit himself to practise medicine? And yet this is the sort of thing that a book of this kind propagates. A man learns a set of answers, parrot fashion, to a set of questions and is sent out to practise a profession. The quiz system at our colleges is liable to just this sort of abuse. When a quiz-master conducts his course for the purpose of getting his men through an examination he is working on fallacious lines. But if a quiz is conducted on lines calculated to assist a student in understanding his subject, to enable him to express himself in good and intelligent English,

and to show him that which he has mastered on the one hand, and that in which he is deficient, on the other hand, the system is productive of good. This applies also to books. A syllabus of a subject or a manual is advantageous to the student because it points out the essential facts of a subject and makes a foundation on which a more detailed superstructure can be reared. But a quiz-compend with its question and its answer destroys originality and kills individual thought, and the book before us is one of the worst features of an abused system. The author's name is properly withheld, and, we venture to think, little credit will accrue to the publishing house for putting the book on the market. [J. M. S.]

Actiologie und Prophylaxe der Lungentuberculose. Etiology and Prophylaxis of Pulmonary Tuberculosis. By DR. J. RUHEMANN, 8 vo., pp. 88. Jena: Gustav Fischer, 1900. Price, 2.50 Mark.

While the doctrine of the specificity of diseases has been more firmly established in recent years it is at the same time recognized that, especially from the prophylactic point of view, attention must be directed to the predisposing and contributory etiologic factors scarcely less than to the exciting causes. In the monograph before us evidence and argument are adduced to show the significant part played, especially by influenza, in the etiology of tuberculosis and as a corollary, the importance of devoting particular care to the prophylaxis and treatment of the former disease under two heads of etiology and prophylaxis, the former in 4 chapters, the latter in one. There are taken up successfully "the inadequacy of existing laws as to the etiology of tuberculosis," "the influence of influenza upon the development of tuberculosis," "the influence of influenza upon the progress of tuberculosis," "the influence of sunlight upon the development and progress of pulmonary tuberculosis," and "the prophylactic measures against tuberculosis." Whether or not one agrees with the argument and the conclusion, the publication will be found to contain much that is interesting and well worth reading. [A. A. E.]

Leukocytosis and the variations of the Polymorphonuclears in Typhoid Fever.—Barbaroux. (*Gaz. Heb. de Med. et de Chirurg.*, March 3, 1901, 48 me., Année, No. 18.) (Lyons thesis, 1900-1901, No. 137.) After a study of the leukocytosis of typhoid fever, Barbaroux concludes: (1) That during the fastigium of the disease there is usually a well-marked hypoleukocytosis, which effects principally the lymphocytes, for although the polymorphonuclears may be reduced in number their percentage is almost always equal to or above the normal. (2) Toward defervescence an increase in the number of leukocytes is seen, which does not, as a rule, however, reach the normal figure. In this stage, also, there is a variable percentage of polymorphonuclears. At the end of this latter period or in the first days of apyrexia, there is a considerable and constant diminution of the total leukocytosis, affecting particularly the polymorphonuclears of which the percentage is very low, usually less than 50%. (3) At the end of several days the number of leukocytes returns to normal or above with a more rapid increase in the number of lymphocytes than of the polymorphonuclears. (4) In benign forms of typhoid fever there may be hyperleukocytosis, as high as 12,000, or hypoleukocytosis, as low as 4,000 during the entire febrile period. If pneumonia occurs as a complication, the number of leukocytes, particularly of the polymorphonuclears, will almost certainly increase. If the complication is due to the bacillus of Eberth, the evolution of the leukocytic curve will correspond to that of a relapse. In grave forms of the disease with relapses, etc., the leukocytic curve is very variable, showing oscillation above and below the normal or a constant hyperleukocytosis. In certain forms of relapse a leukocytic curve similar to that of the first attack is often seen. In certain forms of the disease which end fatally it is impossible to demonstrate a general hyperleukocytosis with an increase of the percentage and of the absolute number of the polymorphonuclears during the latter period of the disease. In all irregular forms hypoleukocytosis is usual during the greater period of the disease. There is, as a rule, no parallel course in the agglutinating curve and the leukocytic curve. On the contrary, it is usual to find that there is considerable lowering of the number of leukocytes when the agglutinating power of the serum is at the highest. [J. M. S.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

College of Physicians.—Sections of Gynecology.—At the monthly meeting held April 18, Dr. R. G. LeConte read a paper on *The value of Hegar's sign in differentiating pregnancy from uterine myoma*. Dr. LeConte spoke of the difficulty in diagnosis when a myoma with little fibrous tissue presented a soft, smooth mass with rounded outline. In some of these there is doubt even when the abdomen is opened. Hegar's sign cannot always be proved or disproved, especially in fat subjects. Its value as a positive sign is unequally rated by eminent authorities. Dr. LeConte has found it of value in 3 cases operated upon for myoma. When the abdomen was opened the uterus appeared so much like a pregnant one that there was some doubt as to the condition present. A search for Hegar's sign showed it to be present in each case and hysterectomy proved each to be a myoma. Dr. C. P. Noble said that he had never seen Hegar's sign present when pregnancy was absent. An early sign of pregnancy upon which he places a great deal of reliance is the semi-cystic feel of the uterus caused by the increasing amount of fluid within. This with the jutting out of the body of the uterus beyond the cervix, due to enlargement, is considered to be the most reliable early sign. Dr. E. P. Davis said that Hegar's sign should be present in all normal pregnant uteri when no adhesions are present and is a most positive sign. Dr. Richard C. Norris stated that Hegar's sign was not of any value to the man who makes casual examinations as it is difficult to elicit and requires a skilled touch. Sometimes anesthesia is necessary. It is of value in association with intermittent contractions of the uterus and increase in size, especially unilateral increase. Dr. A. Ernest Gallant, of New York, read a paper on *the corset for movable kidney*. Dr. Gallant stated that from 90 to 95% of symptomatic movable kidneys can be relieved symptomatically by the judicious use of the corset. The symptoms and diagnosis of movable kidney were considered at length. In speaking of the diagnosis Dr. Gallant recommended to the practitioner the constant practice of abdominal palpation in all cases as well as the examination of heart and lungs. It is only in this way that proficiency in diagnosing pathologic lesions can be acquired. He believes that movable kidney is much more common than is stated. The statistics of 1900 gynecologic cases were given. Of 1000 at one dispensary 21 had movable kidney. Of 800 at another dispensary 7 had movable kidney. Of 100 seen in office practice 21 had movable kidney. The various sets of symptoms in different cases were considered. In 25 out of Dr. Gallant's 41 cases both kidneys were movable. Those cases in which the kidney is at the pelvic brim, as a rule give the least trouble. In speaking of the treatment it was said that fixation only transferred the weight from the vascular pedicle to a cicatrix. This treatment does not achieve all that is desired. Mistakes in diagnosis also make the surgeon hesitate before operating. Mechanical means are considered superior to operative procedure. Belts and pads have their advantages. Corsets are much better and physicians had better teach women to use them properly than to give them up. The prevailing style of corset is a good one for this purpose. It should be as long in front as can be worn. A corset 2 inches smaller than the size usually worn should be selected. The lacing should be from below upward, pushing the kidney well up beneath the ribs before fastening the upper hooks. The corset should be fastened on before the patient rises in the morning. Great attention should be paid to the general health of the patient. Dr. John B. Deaver has had very little success with appliances and prefers to anchor the kidney by means of gauze. Jaundice in movable kidney he believes to be due to a relaxed condition of the peritoneum and its contents which allows the kinking of the duct. The objection to the suture is that it may cause urinary extravasation. The kidney substance is too soft for the stitches to hold and inflammatory tissue is the only real cause of holding even when sutures are inserted. Dr. Chas. P. Noble examined all his patients for one year for movable kidney and found that every fifth one had that condition. He prefers the

patient in the standing position when making the examination. He uses sutures and has never had any untoward results from them. Dr. Shober exhibited a corset designed by a resident of Philadelphia. He believes that retention of urine and distention of the bladder is a cause of movable kidney by inducing absorption of the perirenal fat. Dr. B. C. Hirst spoke of the application of the corset to patients while in the Trendelburg position. Dr. J. M. Baldy stated that movability of the kidney was only a relative question which is settled by the observer's standard as to what constitutes a movable kidney. He does not find any such proportion of cases as were reported. The symptoms of the condition are largely neurotic and he does not see how mechanical appliances are to ameliorate them. Dr. John G. Clark said that the condition was often one of general enteroptosis, especially in women who have some children, hence relief is caused by binders. No operation should be done unless grave symptoms are present. So many women have flat abdomens that it is hard to get the corset to fit snugly. Dr. Geo. F. Shoemaker said that many women cannot wear corsets. Appliances generally have little effect on the kidney. Dr. B. C. Hirst gave a very brief report on the relative merits of the different methods of panhysterectomy in malignant disease of the uterus. Four methods were named—the abdominal, the vaginal, the abdominal and vaginal, and the vaginal and abdominal. The latter is much preferred. It is neater, any enlarged glands can be removed, and convalescence is shorter.

Pediatric Society.—The regular monthly meeting was April 9, the president, Dr. T. S. Westcott, presiding. The address of the evening was delivered by Dr. L. Emmett Holt, of New York, his subject being **some forms of indigestion in infants and young children with especial reference to their dietetic treatment.** Dr. Holt spoke mainly of the chronic forms of indigestion. In regard to the transmission of this condition Dr. Holt believes that direct inheritance is questionable. The progress of an infant during the first year depends upon its condition during the first 3 months, and that upon the start it gets in the first 4 weeks. Dr. Holt is more and more impressed with the sensitiveness of the infant digestive apparatus. Almost as much trouble with infants is caused by bad nursing as by bad feeding. The average obstetrician has but little knowledge of the care needed during the first few days or weeks of an infant's life. To be successful the pediatricist needs to have charge of the infant from the first, and not begin when it is 1 month old. The child can be accustomed to cow's milk only by very careful training. The milk of the Walker-Gordon laboratory is considered to be much better than any other infant food. The initial formula is generally 1% fat, 6% sugar, and .5 proteids. The proof of whether the child is doing well on a certain formula is its degree of comfort. A healthy infant should sleep about 22 out of 24 hours, should not vomit, should have no colic. Sometimes it will be constipated, but this will disappear when the food is made stronger. Is the child entirely comfortable? Then bide the time when it shall gain in weight and do not pay too much attention to constipation. Feeding should be begun at the end of the first 24 hours, and with a strong, lusty child, even before that time. Early feeding helps prevent the initial loss in weight. The symptoms of indigestion may be divided into two groups: those where the stomach is at fault, and those where the intestines are the seat of trouble. Very rarely has gastric dilatation much to do with indigestion. Vomiting is caused more often by a high amount of fat than by any other condition, the organic acids formed from the fat being the cause of trouble. In these cases avoid milk and cream and give milk and water. Stomach washing and in some cases irrigation may be tried. In cases of vomiting from the presence of mucus, stomach washing is the only remedy. Attacks of acute indigestion are dangerous and are often caused by surprisingly small quantities of cow's milk. These cases are generally said to be due to infection from the milk, but other causes may be acting. A case was cited in which a child which had been sick had had a normal temperature for 4 days when one ounce of milk was given and death followed in 48 hours. This was due to a latent condition of the bowels which the milk had caused to be active. Such cases prove that good milk in small quanti-

ties may be poisonous—the fault, however, being not in the milk, but in the child. Attention should always be paid to the previous history of the child. If several attacks of indigestion have been caused by cow's milk, do not begin it at once. Dr. Holt stated that he was a firm believer in the artificial feeding of infants, but that it has its limitations, and a wet nurse is desirable in some cases, though this may be the worst possible expedient in others. Every mother is to use her milk when possible, but this is not always the best for the infant, an immense amount of harm being done by nursing when it should not be done. The best test is the effect of the milk upon the child. Where there is persistent indigestion with no gain in weight, the case is hopeless, and nursing should be stopped. In feeding children with indigestion try less milk with higher percentages and give water between meals. Feeding should not be oftener than once in 2 hours and in the majority of cases 4 hours is better. Some of the points emphasized in conclusion were: (1.) The simplicity of the question of feeding infants when they possess healthy organs and the complexity of the problem when these organs are deranged. (2.) The comfort of the infant is the guide as to the correctness of the feeding. (3.) No mother should nurse an infant which has persistent indigestion and does not gain in weight. (4.) If there is a gain in weight, then try to overcome the indigestion. (5.) There is no more troublesome symptom than vomiting. This is due in the majority of the cases to too large an amount of fat, hence that ingredient should not be increased too rapidly. (6.) Too much attention should not be paid to traditional opinions regarding the amount of fat, proteids, etc. In discussing the paper of Dr. Holt, Dr. J. P. Crozier Griffith said that great care with the minute details of feeding and nursing infants was the cause of success. Constipation in a healthy baby is a sign of assimilation of the food taken, and should be let alone in very many cases. It is the custom now to say that something is wrong with the food when indigestion occurs. Older writers traced many of these cases to taking cold, to wearing certain binders, etc. These points are too often overlooked at the present time. There are undoubtedly many instances in which outside conditions are responsible, and the details of hygiene should be carefully watched. Dr. E. E. Graham spoke of the treatment of acute indigestion. Milk is withdrawn, and sterile water or albumin water, with stimulants if necessary, is given. After a time the use of expressed meat juice is begun, this being followed by peptonized milk. Dr. Alfred Stengel said that the time had hardly been reached when fundamental principles in infant feeding could be dealt with. Efforts in that line are now mainly attempts to cause sick children to thrive on the food of healthy children. The reduction of food should be considered as well as the change in character. Proteid foods and high fat percentages are badly borne in proportion to the degree of inanition present in the infant. Carbohydrates should be increased and the others withdrawn. Dr. Holt said that regarding intestinal lavage, etc., the primary principle to follow was not to do any harm. In cases of summer diarrhea many infants are killed by over-treatment. A child fed by rule can be managed if that principle is started rightly. Hospitals are the poorest places to study infant feeding. Find out what food the child can stand and send it out to return for treatment when necessary.

Resignation of Dr. Risley.—Dr. Samuel D. Risley has resigned from the service of the Philadelphia Polyclinic after a long service as Professor of Diseases of the Eye in that institution. He has been created by the Board of Trustees, Emeritus Professor of Diseases of the Eye. In common with several other members of the Board of Trustees of the Philadelphia Polyclinic, Dr. Risley had also resigned voluntarily in order that the Board might become entirely a body of laymen. Dr. William Campbell Posey was elected to the vacancy caused by Dr. Risley's resignation.

Vital Statistics of Philadelphia for the week ending April 20, 1901:

	Cases.	Deaths.
Inflammation of the appendix 7, bladder 1, brain 16, bronchi 8, heart 1, kidneys 19, liver 3, lungs 47, peritoneum 10, pleura 3, stomach and bowels 13, tonsils 1		132
Marasmus 12, debility 6		18
Tuberculosis of the lungs		75
Apoplexy 17, paralysis 4		26
Heart-disease of 24, dropsy of 2, fatty degeneration of 2, neuralgia of 5		33
Uremia 13, diabetes 2, Bright's disease 7		22
Carcinoma of bladder 1, breast 3, stomach 4, uterus 1, liver 1, penis 1, throat 1, rectum 1		13
Convulsions		17
Diphtheria	48	10
Brain-congestion of 2, disease of 1 softening of 4		7
Typhoid fever	44	8
Old age		17
Cyanosis		1
Scarlet fever	85	3
Abscess of neck 3, pelvic 2, spine 1, alcoholism 1, aneurism aorta 1, asthma 1, anemia 1, atheroma 2, burns and scalds 4, casualties 9, cerebrospinal meningitis 2, congestion of lungs 6, cirrhosis of liver 4, croup, membranous 4, disease of spine 2, drowned 2, erysipelas 1, fever, puerperal 1, indigestion 1, jaundice 2, obstruction of the bowels 1, edema of the lungs 3, poisoning 1, rheumatism 1, sclerosis, arterial 2, septicemia 3, smallpox 1, sarcoma of jaw 1, of uterus 1, suffocation 4, suicide 1, syphilis 1, tetanus 1, unknown coroner case 1, whooping cough 8, wounds, gunshot 1		81

NEW JERSEY.

The Camden City Dispensary.—The Camden City Dispensary, the well-known institution which has been doing such a noble and charitable service for the worthy poor in the city of Camden and vicinity, in need of medical and surgical aid, enters upon the thirty-sixth year of its history with a record creditable alike to the city as well as the physicians who have been energetic in pushing the institution to the front. As early as 1859 Dr. Othniel Hart Taylor called the attention of the Camden City Medical Society to the propriety of petitioning City Council for the establishment of a dispensary. Any institution like this one which ministers to the worthy poor is deserving of the highest commendation.

NEW YORK.

Elected Professor.—Dr. Heinrich Stern has been elected professor of internal medicine in the New York School of Clinical Medicine.

Dr. Frank Wayland Abbott.—Dr. Frank Wayland Abbott, regarded as one of the foremost oculists in Western New York, died at his home, No. 523 Franklin street, on April 9, after a protracted illness. Dr. Abbott was graduated from the University of Buffalo in 1866, and was oculist in chief at the General Hospital and the Eye, Ear and Throat Hospital, of Erie County.

New York School of Clinical Medicine.—The New York School of Clinical Medicine invites the local profession and visiting physicians to the following course of lectures to be delivered every Friday evening in April and May at 6.30, at 323 West 42nd St. April 5th, Examination of the Male Urethra by the General Practitioner, Clinical Demonstrations; Ferd. C. Valentine, M. D. April 12th, Medical Questions of the Responsibility of Alcoholics, Opium and Other Drug Takers, Thomas D. Crothers, M. D. April 19th, Complicated Fractures: Diagnosis and Modern Treatment, Thomas H. Manley, M. D. April 26th, Diagnosis and Surgical Treatment of Prolapsed Kidney: With Clinical Demonstrations, Augustin H. Goelet, M. D. May 3rd, Treatment

of Strangulated Hernia, Carl E. Pfister, M. D. May 10th, Pelvic Trilogy in the Diagnosis of Diseases of Women, A. Ernest Gallant, M. D. May 17th, The Techniques of Major and Minor Amputations, Robert H. Cowan, M. D. May 24th, Treatment of Obesity, Heinrich Stern, Ph. D. M. D. May 31st, Diseases of the Stomach: Practical Examinations and Treatment. Demonstrations on Patients, Freeman F. Ward, M. D. June 7th, Psoriasis and Acne. Effective and Practical Methods of Treatment: Clinical Demonstrations, W. R. Inge Dalton, M. D. Marcus Kenyon, M. D., Secretary.

New York Neurological Society.—Stated Meeting April 2, 1901, Joseph Collins, M. D., President.—**Recurrent Oculomotor Palsy.**—Dr. William M. Leszynsky presented a woman, twenty-nine years of age, whom he had first seen four months ago. When six years old she had begun to have attacks of headache confined to the right temporal and supraorbital regions, and invariably accompanied by vomiting. The attacks occurred every five or six weeks. At her twelfth year the customary paroxysm had been associated with ptosis of the right eye, from which she had recovered in two weeks, the migraine continuing to recur as before. The second attack of oculomotor paralysis had occurred in her nineteenth year, with some pain and vomiting. There were partial ptosis, diplopia and inability to look upward with the right eye. She had improved in three weeks, but the eye did not move upward as well as before for a few months and then there had been complete recovery of motility. The third attack had occurred in her twenty-second year, and had been characterized by almost complete ptosis, outward deviation of the eye and diplopia. She had been obliged to keep the eye covered for three months, but had recovered in about a year. The fourth attack had been two and a half years ago and the fifth only three weeks ago. She now complained of the eye turning outward and of her inability to look upward. The periodical headaches bore no relation to menstruation. Examination showed slight drooping of the right upper eyelid, paralysis of the superior rectus and paresis of the inferior and internal recti. The right pupil is 5 mm. in diameter and rigid, while the left measures 3.5 mm. and reacts normally. Vision is normal in both eyes, and the fields and fundi are normal. She is anemic and neurasthenic. The family history was unimportant, and her ocular condition had practically remained unchanged since the first examination. The speaker said that the most interesting features were the comparative rarity of this type of oculomotor palsy and its pathology. Only two authentic cases of recurrent oculomotor palsy had been studied post-mortem, one by Richter, in 1887, and the other by Karplus, in 1895. In the former, a fibrochondroma existed in the course of the nerve trunk at the base of the skull, and separated but did not destroy the nerve fibres. In the other case, there was a neuro-fibroma of the motor oculi at the base. In many of the reported cases complete recovery had taken place, but in others the paralysis had gradually increased during the intervals, and had ultimately become permanent. Dr. Leszynsky said that he had seen four other cases. In the first, there had been complete paralysis of the third nerve with a clear history of accompanying migraine. Recovery had been spontaneous. Dr. B. Socks said that these cases were extremely rare, though he had been fortunate enough to see two in the past six months. One had been in a boy of four years who within a year had had two distinct attacks of oculomotor paralysis of one eye. He had recovered in a few months from the first attack. The family history was entirely negative. He understood that improvement had followed the second attack. There had been apparently no migraine here. Dr. Leonard Weber said that he had presented a case of this kind to the society twelve or more years ago. The man had oculomotor palsy on the right side. He had watched the case for a number of years. After about two years there had only been a little ptosis remaining. After a course of iodide the man had greatly improved, and had ultimately died of pulmonary tuberculosis. Dr. B. Onuf said that he had presented such a case to the society one year ago. The patient had since been given iodide of potassium in increasing doses, and had moved to the country. The attacks had become shorter and less severe. He did not believe that there was always a lesion of the oculomotor alone. His own case was undoubtedly one of migraine. Dr. Les-

zynsky said that a very novel theory had been brought forward regarding this paralysis occurring in connection with migraine. It had been assumed that there is an increased vascularity of the hemisphere during the attack of migraine, causing a disturbance of the function of the third nerve. **A Case of Malignant Tumor of the Shoulder Perforating the Spinal Canal.**—Dr. Leonard Weber read this report, and presented the specimen. The subject was a man of thirty-one whom he had first seen in 1891. He had presented the usual symptoms of a recent syphilis, and had been treated for this with improvement. In 1894 he had returned because of a perichondritis of the cartilaginous portion of the nasal septum. At this time a small movable tumor, the size of a cherry, was noted in the right shoulder. This was supposed to be gummatous. The tumor diminished under mixed treatment, but a small nodule remained. In June, 1900, the man had sought relief because of a hard, solid and almost immovable tumor of the shoulder, which he said developed shortly after a blow on the shoulder received one year previously. No benefit had resulted from rapidly increasing doses of iodide or from the biniodide of mercury. Three months later a portion of the growth was submitted to microscopical examination, with the result that it was declared by two pathologists to be a round cell sarcoma. An effort had then been made to remove the growth, but this had been found impracticable. Injections of arsenite of soda and carbolic acid had been given for a time, but without benefit. On December 3 he had been admitted to St. Mark's Hospital, because of a suddenly developed paraplegia. Bed sores soon formed and he became septic, and died on February 11, 1901, from exhaustion. The cord symptoms in this case were due to hemorrhage and degenerative myelitis. As to whether the little tumor first felt in the shoulder was specific, the speaker said that this was probable, and added that the case emphasized the desirability of removing apparently innocent tumors at an early stage. **A Case of Cerebellar Apoplexy with Autopsy.** Dr. Weber also made this report. The patient was a man, twenty-nine years old, living amid the most unsanitary surroundings. The urine had a specific gravity of 1024, and contained a slight trace of albumin and some hyaline and granular casts. There was no history of syphilis. He had been sick for about two months before coming under observation on September 11th. There was constant headache, but no sensory or motor disturbances. The diagnosis seemed to lie between tumor, hemorrhage and abscess of the cerebellum. On account of the length of time that he had been sick abscess seemed to be more probable than hemorrhage. He died in a few days, and at the autopsy the entire venous system was found engorged with blood. There was marked hypertrophy of the left side of the heart; no endarteritis of the arch of the aorta; both kidneys were slightly enlarged, the cortex showing proliferation of connective tissue in patches, and presenting the gross appearance of interstitial nephritis. No opportunity was given for microscopical examination. In the substance of the right cerebellar hemisphere was an accumulation of both recent and old coagula, and the apoplectic focus had ruptured into the fourth ventricle. He had seen one case of cerebellar apoplexy in a girl of twenty-five years, who had an unsuspected and untreated syphilis. **A Tumor of the Optic Thalamus.**—Dr. Joseph Fraenkel presented this specimen, which had been taken from a person whom he had shown to the society in January, 1898. At that time the boy had had the cardinal symptoms of brain tumor, and a paralysis of the face which was very marked when there was any emotional disturbance. There had been no hemianopsia. The boy had been discharged from the Montefiore Home, and had done fairly well for two years and a half. When readmitted, there had been very nearly the same symptoms as before, and in addition a much more marked unsteadiness of gait and a disposition to fall to the right side. Dr. Fraenkel said that it had been said that he had been led to think it possible that the tumor was after all situated in the cerebellum. On removing the brain at autopsy, a very old cyst was found on the fourth ventricle, the exact nature of which had not yet been determined. There was also a large tumor occupying the right optic thalamus. **Spinal Cord Showing Result of Fracture, Dislocation of the Cervical Spine.**—Dr. Edward

D. Fisher reported this case and presented the specimen. The patient was an acrobat, twenty years of age. While turning a somersault from the shoulders of a companion he had fallen a distance of about five feet, and struck on his head. He was instantly paralyzed. When seen by the speaker that evening there had been complete anesthesia from below the nipple extending down the arms to the armpit, and on the inner side of the arm and forearm, and taking in the ring and little fingers. There was complete loss of motion and paralysis of the bladder and rectum. The reflexes, superficial and deep, had been completely lost. Permission could not be obtained for operation until three days later, and in the meantime there had been a temperature range of 104° or 105°F. The operation had been done by Dr. B. F. Curtis under cocaine anesthesia, and the laminae of the fifth, sixth and seventh vertebrae removed. No evidence of injury to the cord could be discovered. The man died three days later. The autopsy had revealed a fracture of the body of the seventh vertebra, no subdural hemorrhage, marked softening of the cord at the seventh cervical segment. There was very little gray matter left in the cord at that level, and there was very little evidence of hemorrhage into the cord-proper. A very prominent symptom had been the extreme pain experienced along the course of the nerves. The classical distribution of the paralysis and the complete loss of reflexes were interesting features. Dr. B. Sachs remarked that twenty years ago it had been pointed out that a very significant symptom of the disease of the optic thalamus was this peculiar facial palsy made visible by emotion. Dr. Leszynsky said that he had seen recently a case of dislocation in the dorsal region with loss of reflexes and paralysis below the seat of injury. An operation had been done, but death had followed. The autopsy had revealed a complete transverse destruction of the cord. Dr. Fraenkel said that some time ago he had presented a paper to the society on this matter of the reflexes, and had continued to give a good deal of attention to this subject. He would assert that the skin reflexes are not lost in total destruction of the cross section of the cord, and the relation of the tendon reflexes to the skin reflexes should enable one to decide whether or not the cord has been completely destroyed in this manner. When the compression of cord was sufficiently great to interfere functionally with conduction upward and downward, the tendon reflexes are lost while the plantar reflexes are exaggerated. When, however, there is structural disease of the entire cross section of the cord, the plantar reflexes are also lost. This he considered a valuable point in the differential diagnosis. He had reported two cases with autopsies in which there had been loss of reflexes without total abolition of the conduction in the cord. Dr. Leszynsky said that in the case he had just referred to all forms of reflexes had been abolished, both superficial and deep. **Brain From a Case of Epilepsy Operated Upon.**—Dr. H. L. Winter exhibited this specimen, which had been taken from a child of seven years. All of the head measurements were small; there was no paralysis of any of the muscles. The child was an imbecile and had epileptoid seizures which appeared to be general. Dr. Stewart had operated upon the child at Bellevue Hospital. On reaching the brain a large cyst cavity had been found in the left hemisphere. The child died seven days later with a high temperature. The hemisphere was found to have been nearly destroyed by the cyst, and the convolutions were not well marked. The interesting feature was the almost complete destruction of the hemisphere without any paralysis. The fibres of the medulla were found not to decussate as freely as usual. **Abscess of the Brain.**—Dr. Joseph Collins presented this specimen. It had been impossible to make a localizing diagnosis. The patient was a man, twenty-seven years of age, a tailor by occupation. Two weeks before admission he had been suddenly seized with severe and more or less paroxysmal headache distributed over the whole head. The pain was almost intolerable for six days, and then he became dizzy and had projectile vomiting without nausea. There had been some whistling sound in the right ear. When seen by the speaker, four days after coming into the hospital, there was double choked disk, but no hemianopsia. There was no leukocytosis, although the hemoglobin percentage was 36. Apparently there was no impairment of hearing. The knee jerks were normal. There was no evidence of palsy

or of spasm in any part of the body, and no symptoms referable to the special senses. The patient died four days later of exhaustion. The autopsy revealed an abscess situated in the right hemisphere, and involving particularly the posterior end of the inferior parietal lobe and of the superior parietal lobe. The cuneus itself was partly implicated. The teat-like extremity of the cuneus, it should be noted, was entirely intact on the side of the abscess cavity, and if the optic radiations are not cut across it would not be difficult to explain the absence of hemianopsia. A diagnosis had been made of abscess of the right superior parietal convolution. Dr. Fisher said that both the superficial and deep reflexes had been absent in his case, and it was because of this that he had inferred that there was complete destruction of the cord. The operation had been undertaken to relieve intense pain.

WESTERN STATES.

Bullet in His Heart.—Evidence that a man may live with a bullet in his heart was afforded by the use of the X-ray upon Charles B. Nelson, of Cadillac, Mich., who in 1896 was the central figure in a sensational shooting that nearly resulted in his death. Under the fluoroscope the ball in Nelson's heart could be plainly seen rising and falling with each pulsation of the vital organ. The bullet has been there since the night of July 1, 1896.

Licenses Refused.—Seven graduates of the Pacific Coast Regular College of Medicine, comprising the first graduating class of that institution, which began its work only about nine months ago, have been refused licenses to practice by the Board of Medical Examiners of the Medical Society of the State of California, on the ground that their alma mater does not meet with the minimum requirement for medical colleges, as adopted by the Board December 4, 1900.

Meeting of the Chicago Pathological Society, Monday, April 8th, 1901. Dr. L. Hektoen, President.—Dr. Bertha E. Bush reported a case of varicose veins of the right upper extremity in a child. This report places upon record a case of developmental varix, in a young child, the process affecting the anterior superficial veins of the entire right hand, arm and shoulder. Numerous sacular dilatations occur just beneath the skin, those at the inner end of the clavicle and in the palm of the hand being the most conspicuous. Skiagraphs show deformity of the right metacarpal bones, and generally diminished growth of the arm and hand. There is no pulsation or edema, and no history of hemorrhage. Noteworthy points in the case are: 1. The congenital origin. 2. The region involved. 3. The obscure etiology. 4. The scarcity of literature.

Dr. H. T. Ricketts presented a consideration of **Blastomycetic (Oidiomycetic) dermatitis and its organisms**, with demonstrations. Through courtesies from Professors Hyde, Montgomery and Hektoen, he had studied the pathological and mycological features of ten new cases of Blastomycetic (Oidiomycetic) Dermatitis observed during the last 18 months, mostly in the clinics of Profs. Hyde and Montgomery. The work was done in the pathological laboratory of Rush Medical College. There is a uniform clinical history in all cases; the process beginning as a pustule, which becomes a large ulcer, the surface later being covered with coarse papillae bathed in pus. A reddish areola containing milium abscesses surrounds the verrucose tissue; the centre of the lesion cicatrizes as the periphery extends. The histological features are uniform; carcinomatoid proliferation, and leukocytic infiltration of the epithelium, intra-epithelial abscesses, premature and abnormal cornification, peculiar retrogressive epithelial changes and epithelial giant cells, and in the corium, dense leukocytic and plasma-cell infiltration, fixed tissue proliferation, subcutaneous abscesses, giant cells and tubercles, resembling those of tuberculosis, but being less typical in the inter-relationship of cells and showing less advanced regressive changes. Plasma-cells seek the periphery of the process. Apparently there is an eosinophilous type of the disease, which, in the case studied, is associated with a mould fungus form of the parasite, and very large papillae. Russell's fuchsin bodies are found in plasma-cells and intercellular spaces. There is a close relationship between the plasma-cells and the formation of a peripheral protective zone of fibrous tissue. They do not appear to become fibroblasts, but to undergo a gradual disintegration as provender for forming fibrous

tissue. Mast-cells exist in large numbers, and are classified as 1, leukocytic; 2, connective tissue cell type; 3, those possessing halos; and, 4, the plasma-mast-cell type. In the tissue the organisms are found singly, in budding pairs and in groups, in intra-epithelial and subcutaneous abscesses, free between healthy rete cells, in giant cells, and in the granulation tissue of the corium. From seven cases the organisms have been cultivated. They fall into three groups: 1, the yeast-like, resembling those of Hektoen, Hessler, Busse and Curtis; 2, the odium-like; 3, the mould-fungus type, resembling the organism isolated by Ophuls and Moffit from the protozoic (?) disease. Study shows that all these have common generic properties, and are separated only by specific characteristics which are more or less variable. In accordance with pre-existing nomenclature they all belong to the genus *oidium*. "*Blastomyces*" is considered not sufficiently inclusive. Pure cultures inoculated into animals produce local abscesses, septicemia, or, if injected into veins, mycotic nodules and consolidation in the lungs. The various methods of proliferation in cultures are, germination, lateral conidia, terminal spore-groups, abjunction of mycelial segments, aerial conidium-bearing hyphae (in the mould-fungus, and questionable endogenous spore-formation. Of many inoculations of tissue from man into guinea pigs, none have resulted in tuberculosis. A study of Busse's case of "*Sacchromycosis hominis*," of the protozoic (?) disease of Wrenicke, Gilchrist, Ophuls and Moffit, and others, and of Blastomycetic dermatitis, together with the fungi concerned in all, affords convincing evidence that the three are closely related processes, caused by similar organisms; the protozoic (?) disease and *Saccharomycosis hominis* (Busse) are examples of the generalized infection, while Blastomycetic dermatitis (Gilchrist) is a local manifestation of the disease. The term *Oidiomycosis* is suggested as a name for the combined manifestations. Cultures, as well as gross and microscopic specimens of tissues were exhibited. Discussion of paper by Dr. H. T. Ricketts. Dr. Maximilian Herzog: If so many varieties of organisms are found in cases of clinical blastomycetic dermatitis, they can not be a single disease which is due to a single cause. Dr. Coates objected to the term *oidiomycosis* as liable to introduce confusion. Dr. Ricketts, in closing, said he did not insist on the use of the term *oidiomycosis*. He considered the protozoan diseases as due to an organism very closely related to the ones under consideration. Dr. L. M. Loeb reported two cases of infection by the *bacillus aerogenes capsulatus*. (1) A compound fracture of both bones of the forearm was followed by emphysema of the whole extremity in two days. Recovery took place uninterrupted after shoulder amputation. (2) An abrasion of the outer side of the knee was followed in one day by phlegmonous emphysema of the entire leg and by constitutional symptoms of profound intoxication. Fifteen to twenty short incisions were made and drainage of bichloride dressings employed. In ten days gas bacilli and emphysema were gone and recovery interrupted only by a suppurative of the knee joint which took place. This case again brings up to consideration the more conservative methods of treatment. Discussion of the paper by L. M. Loeb. L. F. Barker spoke on the circumstance of the discovery of the organism. He urged early recognition of the disease and treatment. Dr. Gideon H. Wells mentioned a case in which the emphysema was first noticed in the subcutaneous tissue of the left shoulder, extending some distance in the course of a few days. Because of the finding of pulmonary tuberculosis, it was suspected the emphysema was due to a tuberculous abscess connected with the chest wall, which had ruptured. At autopsy this was found to be not the case, but due to the *bacillus aerogenes capsulatus*.

Missouri State Medical Association.—The programme for the Jefferson City meeting is as follows: Call to order at 9.30 A. M.

FIRST DAY.

MORNING SESSION.

Invocation—Rev. A. H. Barnes.

Reading of Minutes.

Report of Chairman of Committee of Arrangements.

Address of Welcome.—Gov. A. M. Dockery.

Report of Treasurer.

Appointing Committees: (a) Auditing Committee; (b) Vacancies on Committee on Credentials; (c) Special Committees.

Report of Committee on Scientific Communications.

Report of Committee on Publication; B. C. Hyde, Kansas

City, chairman; F. J. Lutz, St. Louis; H. W. Loeb, St. Louis.

Report of Committee on Credentials.

Election of Officers. (Can be made a "special order of business" for some other hour by a two-thirds vote).

Miscellaneous business.

AFTERNOON SESSION.

Report of Committee on Credentials.

1. Report of Committee on Progress of Surgery—J. D. Griffith, Kansas City, chairman. Discussion opened by F. J. Lutz, St. Louis, and C. H. Wallace, St. Joseph, committee.

2. The Epidemic of So-Called Smallpox—J. D. Brummall, Salisbury. Discussion opened by S. C. James, Kansas City.

3. Treatment of Acute Insanities—John Punton, Kansas City. Discussion opened by C. H. Hughes, St. Louis.

4. (a) Intestinal Obstruction—H. Clay Dalton, St. Louis.

(b) Intestinal Obstruction following Abdominal Section—Edward Wallace Lee, St. Louis. Discussion opened by O. Beverley Campbell, St. Joseph.

5. Entropion and Ectropion—Flavel B. Tiffany, Kansas City. Discussion opened by Carl Barck, St. Louis.

6. (a) The Value of Venesection and Saline Injections in the Treatment of Pneumonia—and addition to the paper read before the association last year—William Porter, St. Louis.

(b) Treatment of Pneumonia—H. W. Latham, Latham. Discussion opened by C. F. Wainwright, Kansas City.

7. Peculiar Nervous and Urinary Manifestations in the Aged Following La Grippe—O. P. Kernodle, Sedalia. Discussion opened by Thomas Chowning, Hannibal.

EVENING SESSION.

8. Demonstration of Kidney Lesions with Stereopticon—M. Dwight Jennings, St. Louis.

9. President's Address—U. S. Wright, Fayette.

SOUTHERN STATES.

Physician Assassinated.—Dr. H. S. Scruggs, Jr., who resided at Aulona, a suburb near Memphis, Tenn., was found sitting upright in his buggy near his home on April 17th, with a bullet hole behind the left ear. His horse wandered along the roadway for several hours before the crime was discovered.

Cecil County Medical Society.—The Cecil County Medical Society has elected Dr. Joseph W. Wallace, of Chesapeake City, president; Dr. John H. Jamar, of Elkton, treasurer, and Dr. H. P. Hinchcliffe, of Elkton, secretary.

Oral College Examinations.—The faculty of the Medical College of Virginia have recently decided to examine members of the graduating class by oral, instead of written examinations, as has been the custom until now.

Relief Bills Contemplated.—A meeting of a joint committee representing the medical, dental, pharmaceutical and legal professions, was recently held at Richmond, Va., for the purpose of thoroughly organizing these different bodies for better protection. The new State constitutional convention meets early in June, and it is hoped that a plank may be inserted in the constitution whereby the granting of special privileges and the passing of private relief bills allowing certain persons to practice without standing the required examination, may be abolished.

MISCELLANY.

Appointment.—Dr. Aristides Agramonte, formerly Chief of the Bacteriological Laboratory, has been appointed to the Chair of Bacteriology and Experimental Pathology in the Medical Faculty of the University of Havana, Cuba.

Obituary.—Dr. J. B. Wait, at Medford, Ore., on April 5, aged 59 years.—Dr. Block, of San Francisco, Cal., at Berlin, Germany, on April 12.—Dr. Charles Kelly Gardiner, at Huntingdon, W. Va., on April 14.—Dr. B. E. Lusk, at Lone Oak, Mo., on April 15.—Dr. George W. Cox, at Philadelphia on April 19, aged 61 years.—Dr. John P. Robb, at Fredericksburg, Va., on April 18, aged 80 years.—Dr. L. R. Kirk, at Elkton, Md., on April 19, aged 69 years.

Charges in the Medical Corps of Navy for Week Ended April 20, 1901:

P. A. SURGEON N. J. BLACKWOOD, detached from Naval Hospital, Philadelphia, April 17, and ordered to the Alliance.

P. A. SURGEON L. MORRIS, detached from the Naval Academy, and ordered to Naval Hospital, Philadelphia, April 17th.

ASST. SURGEON A. E. PECK ordered to the Pensacola. SURGEON J. F. URIE, detached from the Dolphin, April 20, and ordered to the Marine Recruiting Rendezvous, Boston, April 22.

SURGEON E. P. STONE, detached from Naval Dispensary, Washington, and ordered to the Dolphin, April 20th.

SURGEON F. ANDERSON, ordered to the Naval Dispensary, April 19th.

SURGEON J. E. GARDNER, detached from Marine Recruiting Rendezvous, Boston, and ordered to Naval Hospital, Cavite, P. I., May 11.

DR. C. G. SMITH, appointed Assistant Surgeon from April 12, 1901.

SURGEON W. F. ARNOLD, from New Orleans to Olongapo, P. I., Sta.

P. A. SURGEON A. ALFRED, to duty with Marine Brigade, Cavite, P. I.

ASST. SURGEON E. J. GROW, detached from the Glacier, and to the Isla de Luzon.

ASST. SURGEON J. STEPP, detached from duty with 1st Regiment of Marines, and ordered to the Castine.

ASST. SURGEON H. C. CURL, detached from the Castine and ordered to the Naval Station, Cavite, P. I.

Official List of the Changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 days ended April 18, 1901:

G. T. VAUGHAN, surgeon, reassigned to duty in the Marine Hospital Bureau, April 13, 1901.

H. D. GEDDINGS, passed assistant surgeon, directed to proceed to Buffalo, N. Y., for special temporary duty in connection with the installation of the Marine Hospital Service exhibit at the Pan-American Exposition, April 18, 1901.

RUPERT BLUE, passed assistant surgeon, directed to proceed to San Francisco, Cal., and report to Surgeon J. H. White for special temporary duty, April 16, 1901.

H. B. PARKER, assistant surgeon, directed to proceed to San Francisco, Cal., and report to Surgeon I. H. White for special temporary duty, April 15, 1901.

M. H. FOSTER, assistant surgeon, 2 days of the leave of absence granted Assistant Surgeon Foster by Bureau letter of March 11, revoked—April 18, 1901.

G. H. CORPUT, assistant surgeon, directed to proceed to San Francisco, Cal., and report to Surgeon J. H. White for special temporary duty—April 15, 1901.

DUNLOP MOORE, assistant surgeon, relieved from duty at Port Townsend quarantine, and directed to proceed to San Francisco, Cal., and report to Surgeon J. H. White for special temporary duty—April 18, 1901.

T. D. BERRY, assistant surgeon, granted leave of absence for 30 days from May 2—April 13, 1901.

J. C. BALLARD, acting assistant surgeon, leave of absence granted acting assistant surgeon Ballard by Bureau letter of February 4th, amended to read—6 days from April 23—April 16, 1901.

B. W. GOLDSBOROUGH, acting assistant surgeon, granted leave of absence for 7 days—April 13, 1901.

R. H. MCGINNIS, acting assistant surgeon, directed to proceed to St. Augustine, Fla., for special temporary duty—April 12, 1901.

RICHARDSON, S. W., hospital steward, directed to proceed to Buffalo, N. Y., and report to Passed Assistant Surgeon H. D. Geddings for special temporary duty—April 17, 1901.

L. P. HALL, hospital steward, directed to proceed to Boston, Mass., and report to medical officer in command for duty and assignment to quarters—April 13, 1901.

APPOINTMENT.

LOUIS P. HALL, of New York, appointed Junior Hospital Steward in the U. S. Marine Service—April 12, 1901.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended April 20, 1901:

SMALLPOX—UNITED STATES.

			Cases.	Deaths.
CALIFORNIA:	San Francisco	Mar.30-Apr.13	5	
DISTRICT OF				
COLUMBIA:	Washington ..	Apr.6-13	1

GREAT BRITAIN.

Re-election.—Sir William Selby Church, Bt., has been re-elected president of the Royal College of Physicians, of London.

Now a British Subject.—Sir Felix Semon, whose appointment as Physician Extraordinary to the King was announced, has become a naturalized British subject.

BRITISH CONGRESS ON TUBERCULOSIS.

PRELIMINARY PROGRAMME.—SECTION I.

STATE AND MUNICIPAL.

Meetings to be Held Daily from Tuesday, July 23d, to Friday, July 26th, from 9.30 to 2.

In this section detailed consideration will be given to the following question, and resolutions relative thereto will be submitted when deemed necessary.

Division I.

STATISTICAL.

What conclusions may be drawn from the statistics available as to connection between the Mortality from Phthisis and the conditions contributing to it?

In this connection regard will be had to the following points:

1. The behaviour of Mortality from Phthisis in England and Wales during the reign of Her late Majesty Queen Victoria.
2. The Geographical Distribution of Phthisis in England and Wales.
3. The Incidence of Phthisis Mortality in particular occupations.
4. The Age and Sex Distribution of Phthisis.
5. The Distribution of Phthisis in the several Sanitary Areas of London.
6. The Statistical Evidence against Heredity of Phthisis.
7. *Tubercles mesenterica* in relation to Milk Supply.
8. A Statistical Study of Phthisis in relation to Soil.
9. The Indications for Future Statistical Research.

Section II.

MEDICAL, INCLUDING CLIMATOLOGY AND SANATORIA.

On Tuesday, the 23rd July, a discussion on "Climatology" will be opened by Dr. C. Theodore Williams and Dr. Burney Yeo: "What Influence has Climate on the Treatment of Consumption, and how far can cases be grouped for Treatment in certain climates?"

On Wednesday, a discussion on "The Therapeutic and Diagnostic Value of Tuberculin in Human Tuberculosis," uniting with the Section of Pathology, to be opened by Dr. Heron. Professor Koch, of Berlin, has consented to take part in the discussion.

On Thursday, a discussion on "Sanatoria for Consumption" will be opened by Professor Clifford Allbutt.

On Friday, Papers.

Demonstrations will be given on—"Cases of Skin Tuberculosis and their Treatment." "The Use of Roentgen Rays in Diagnosis."

If you are desirous of joining in any particular discussion, or of reading a paper, please communicate with the Secretaries of the Section.

Section III.

PATHOLOGY, INCLUDING BACTERIOLOGY.

Tuesday, July 23rd:

"The Morphological and Physiological Variations of the

Bacillus tuberculosis, and its Relations—

(a) To other 'acid-fast' bacilli.

(b) To the ray fungus and other streptothrices."

To be opened by—

Dr. Alfred Moeller, Dirig. Aarzt der Heilstaette, Belzig, bei Berlin.

Dr. William Bulloch, Bacteriologist and Lecturer on Bacteriology and General Pathology to the London Hospital.

Wednesday, July 24th:

"The Tissue-changes and Constitutional Effects produced by the various constituents of Tuberculin."

Joint Discussion in common with the Medical Section, to be opened by Professor Koch.

Thursday, July 25th:

"The Varieties of Tuberculosis (Morbid Anatomy and Histology)."

To be opened by—

Professor Dr. C. Benda, Urbankrankenhaus, Berlin.

Professor Sheridan Delephine, Professor of Pathology, Victoria University (Owens College, Manchester).

Professor D. J. Hamilton, Professor of Pathology, University of Aberdeen.

Friday, July 26th:

"Mixed Infections in Tuberculosis."

Amongst others who are expected to take part in the work of this Section are Dr. Roux and Prof. Metchnikoff, of the Pasteur Institute, Paris.

In addition to the papers in the above subjects the Secretaries are prepared to receive papers on other points of Tuberculosis, which will come on for discussion after the official subjects have been disposed of.

Section IV.

VETERINARY (TUBERCULOSIS IN ANIMALS).

Tuesday, July 23rd.

Subject for discussion—

"The Diagnosis of Tuberculosis in Animals during Life."

This will be opened by Professor Dewar, F. R. C. V. S. Principal of the Royal (Dick's) Veterinary College, Edinburgh, and amongst those who are expected to take part in the discussion are:

Professors McFadyean, Penberthy, Edgar, McEachran, and McLauchlan Young; Messrs. Abson, Blower, Clarke, Dunstan, Fraser, Goodall, Harding, Hicks, Laithwood, Sessions, J. F. Simpson, and Villar.

Wednesday, July 24th.

Subject for discussion—

"Tuberculosis and the Milk-Supply."

This will be opened by Mr. Jno. A. W. Dolar, M. R. C. V. S., and amongst those who are expected to take part in the discussion are:

Professors McFadyean, Stockman, and McLauchlan Young; Dr. McCall; Messrs. Laithwood, Martin, P. Simpson, Sessions, and Villar.

Thursday, July 25th.

Subject for discussion—

"Tuberculosis and the Meat Supply."

This will be opened by Mr. James King, M. R. C. V. S. Chief Veterinary Inspector to the Corporation of the City of London, and amongst those who are expected to take part in the discussion are:

Professors McFadyean, Penberthy, Williams, and Stockman; Messrs. Hunting, Malcolm, Shaw, and Wolstenholme.

Friday, July 26th.

Subject for discussion—

"The Legislative and other Measures necessary to Combat Tuberculosis amongst Animals."

This will be opened by Professor McEachran, F. R. C. V. S., D. V. S., Chief Veterinary Inspector to the Canadian Government, and amongst those who are expected to take part in the discussion are:

Professors McFadyean, Williams, and Edgar; Colonel Nunn; Messrs. Abson, Butters, Hunting, Shipley, Tutt, Villar, and Wolstenholme.

The official languages of the Congress will be English, French, and German, and authors of papers are requested to supply beforehand abstracts for translation. Each speaker opening a discussion will be limited to thirty minutes, and each subsequent speaker to ten minutes. An abstract of every paper and communication must be sent to the Secretary-General, 20 Hanover Square, at the latest on or before June 15th, 1901.

MUSEUM.

In connection with the Congress it has been decided to form a temporary Museum illustrating the Pathology, Treatment, or Prevention of Tuberculosis.

The Museum will consist of—

Section I.—Pathological and bacteriological preparations and specimens illustrating Tuberculosis in man and animals.

Section II.—Plans and models of hospitals and sanatoria, charts, and documents bearing upon the historical, geographical, and statistical aspects of the subject.

It is hoped that any preparations or specimens in connection with work contributed to the Congress will be exhibited in the Museum.

A fully descriptive Museum Catalogue will be published. It is desirable, therefore that all descriptions should be forwarded at the latest on, or before, **June the first**.

Definite information about the date and place for forwarding exhibits will be sent to intending exhibitors. In the meantime the Museum Committee are anxious to obtain as much information as possible concerning the material available for exhibition and the amount of space required.

RUSSIA.

In Favor of an Occasional Drink.—The petition sent to the Military Cabinet by the Society for the Protection of Public Health, asking that the customary drink of *wodka* given to the soldiers be discontinued, was declined on the ground that the amount of alcohol given to each soldier is small, and that he gets that at infrequent intervals. Such a moderate consumption of liquor, the government thinks, is harmless.

An Asylum for Prematurely-born Babies.—The City Council of St. Petersburg made an appropriation of 8,000 roubles (\$4,000) a year for the erection and maintenance of an asylum for prematurely-born children.

American Filters are Bad.—A commission of sanitary specialists in Moscow decided against the use of American filters which, they claimed, are ineffective.

Foreign Skill Invited.—Prof. Bergmann was called out to attend to the wound received by the Minister of Public Instruction at the recent riots. Several well-known Russian physicians are also in attendance. The *Vratch* is quite indignant over this lack of confidence in home talent.

Good Results Obtained in the Sanitarium-Treatment of Tuberculosis.—The results obtained in Chail's Sanitarium for Consumptives seem to be very encouraging, indeed. During a period of 8 years the number of cured and improved reached 84.4%.

CONTINENTAL EUROPE.

Retirement of Professor Ostroumoff.—Professor Ostroumoff, of Moscow, retires this year from his connection with the medical faculty after forty years of service.

French Ophthalmological Society.—The French Ophthalmological Society will hold its eighteenth annual meeting this year in Paris, on May 6. The subject proposed for discussion is the value of iridectomy in glaucoma, to be introduced by M. De Wecker.

New Surgical Invention.—According to the *London Globe*, a sewing machine for the skin has been recently invented by Dr. Paul Michel, who exhibited it at the late Congress of Medicine.

Congenital Cystic Degeneration of the Uterus.—Voskresensky (*Kienskia Universitetskia Izvestia* July, 1900) observed this rare condition in the body of an old woman who died of chronic Bright's disease. The walls of the entire uterus were found composed of small cysts filled with a gelatinous substance. Microscopically, the walls of the cysts were found covered with cylindrical epithelium. The structure was fibroid in character and only here and there a few muscular bundles in a state of atrophy. The author attributes this congenital degeneration to the accidental presence of Wolffian bodies in the embryonic uterus at the time of intrauterine development. [A. R.]

1.—Ballantyne remarks that the Promaternity Hospital need not be a separate establishment; it may quite well be an annex of the maternity, and in time may come to be of equal size as the maternity. It must, however, be distinct from the latter, and will be intended for the reception of women who are pregnant but who are not yet in labor. In time it may be taken advantage of by more or less normal ambulances, as working women who ought to rest during the last weeks of pregnancy but who are unable to do so from financial reasons. Ballantyne remarks that practically no provision is made in existing hospitals for pregnant women. This idea of the pro-maternity hospital has been forced upon him by communications from medical men in England and the United States. Such a hospital, he suggests, would be an excellent place in which to study the pathology of pregnancy, such as placenta previa, albuminuria, and the pre-eclamptic condition. [W. A. N. D.]

2.—Bland-Sutton records a most interesting case of a uterus containing 120 fibroids which he removed by hysterectomy. Four sessile tumors projected into the cavity of the uterus, and these had become so moulded to each other as to form facets on their contact-surfaces such as are found in multiple gall-stones. After hardening the uterus in methylated spirit sections were made from which a careful computation showed the uterus, which scarcely exceeded the dimensions of a fist, to contain 120 fibroids. In all that were examined the tumor-cells were found disposed around the blood-vessels. Each minute fibroid was globular, and one section quite white, so that the contrast in color with the red of the uterine muscle fiber made them conspicuous objects on the cut-surface. Each fibroid was sharply differentiated from the uterine tissue by a thin capsule, from which it could be readily enucleated. [W. A. N. D.]

3.—Lyle divides placenta previa into two varieties, the complete and the incomplete, and remarks that the diagnosis is not difficult but depends on the fact of being able to feel the placenta attached to the lower uterine segment. Carcinoma of the cervix causing hemorrhage in advanced pregnancy might be possibly mistaken for placenta previa, but a careful examination would elicit the true nature of the case. The prognosis for the mother depends on the variety, the complete form being more dangerous than the incomplete; on the treatment adopted, any form of mechanical dilatation of the cervix or the rapid extraction of the child, being extremely dangerous to the mother's life; on the amount of interference; and on early treatment. The prognosis as regards the child, depends on the period of pregnancy, the amount of hemorrhage, and the rapidity of labor. As regards treatment the advantage of version and bringing down a foot, are as follows: 1. It does away with the tampon, and consequent danger of infection. 2. It allows early opera-

tion. 3. It arrests the hemorrhage with great certainty. 4. It gives time for the patient to rally. 5. It gives time for the labor pains to set in with consequent natural dilatation of the cervix. 6. There is less danger of post-partum hemorrhage. [W. A. N. D.]

4.—Fraser records a case of puerperal infection treated by Pryor's method. The infection was probably from a case of appendicitis which had been dressed by the physician prior to his attendance upon the labor case. The operation consisted in opening of the posterior cul de sac and the application of antiseptic dressings under chloroform anesthesia. Following this an ice-bag was placed over the abdomen and from a pint to a quart of normal saline solution injected every eight hour into the cellular tissue of the back. The patient made a good recovery. [W. A. N. D.]

5.—Slight speaks of Hart's observation, namely, that the wall of the third-stage uterus is thinner at the placental site than it is elsewhere above the retraction ring. The placental site is about one-quarter of an inch in thickness while the rest of the wall is four times thicker. Slight believes that in this fact he has found the key to the mechanism of the third stage of labor. The hypothesis which he advances is that during the pain the thin part of the wall is stretched by the thicker part and the placenta and uterus is thereby torn through. The placenta is firmly grasped by the encircling uterus and cannot move, hence as the placental site stretches separation must follow. [W. A. N. D.]

6.—Patch records a case of extrauterine pregnancy on the left side. The operation was performed at the patient's home and the foreign body allowed to escape in piecemeal. Notwithstanding the unfavorable surroundings, the patient made a good recovery. [W. A. N. D.]

8.—While compulsory notification, accompanied by hospital treatment, has lowered the mortality of scarlet fever it has undoubtedly altered the type of the disease. So much so that now it is often difficult to tell when one has, or has not, to deal with the suspected disorder. On every side one hears it repeated that epidemics are now characterized by a want of symptoms and signs. The bright red rash is seldom seen, and when there is a rash it often disappears before the arrival of the medical attendant. If one looks for throat signs they, too, may have been transitory. The symptoms of onset are so slight that even an anxious parent takes no notice of a passing day's indisposition. In fact, the only points that guide one are the existence of cases in the same school or neighborhood, with perhaps slight pain and stiffness due to an enlargement of the glands about the neck. It is these mild cases that kindle into flame the big epidemics that are becoming only too prevalent in big towns. In Paisley, in 1900, the cases of scarlet fever were of mild character and seemed to William Robertson to be a hybrid between scarlet fever and epidemic roseola. Desquamation was indisputable, however. The infection was probably propagated through the summer playgrounds. The erection of high tenements in large towns only encourages the spread of such diseases scarlet fever, measles and whooping-cough. [J. M. S.]

9.—Otto F. F. Gruenbaum uses a mixture of ox-serum, glucose and milk with liquor pancreaticus for rectal feeding. Ox-serum contains a constant amount of proteid which is easily absorbed by the mucous membrane of the large intestine. It does not give rise to offensive stools, which is often the case when egg albumin is used. By injecting 90 ccm. every 4 hours, 540 ccm. of serum is introduced in the 24 hours, which contains 38 grams of pure proteid. By adding 60 ccm. of milk to each enema the total proteid in the diet would be raised to 51 grams. Examination of washings for the rectum showed that less than a gram of proteid was excreted unaltered. In no case did a rash appear nor any albuminuria or albumosuria. Carbohydrates in the form of starch or glucose are readily absorbed. The author has given 30 grams, all of which was absorbed without the production of glycosuria. Fat is not easily absorbed; of the 18 grams in the milk, some has invariably been returned in the wash-out enemata. The heat value of the above diet is 578 calories. This may be increased by another 300 calories by the subcutaneous injection of sterilized olive oil; 30 or 40 ccm. of which may be given daily. [J. M. S.]

10.—d'Esterre reports the case of a woman, aged 35

years, who had had rheumatism, influenza, pneumonia, pleurisy, muscular rheumatism and constantly recurring sore throat. When first seen she complained of sore throat, and her temperature was 103°. Both tonsils were considerably swollen and almost completely covered with a distinct yellowish membrane-like deposit. Bacteriological examination of the membrane did not show diphtheria bacilli, but resulted in an abundant growth of streptococci. Fifteen hundred units of antidi-phtheritic serum were given before the results of the bacteriological examination were known, and the patient made a rapid and complete recovery. Five months later the patient had a second attack exactly similar to the first. Bacteriological examination gave the same results and the same dose of antidi-phtheritic serum was followed by complete and rapid recovery. [J. M. S.]

2.—Kelly concludes that the pharynx may reveal sclerotic hyperplasia without the association of syphilis, rhino scleroma, or other infectious diseases. Similar sclerotic hyperplasia may show itself beneath the vocal cords as subglottic hypertrophic laryngitis. Histologically, the hyperplasia due to syphilis closely resembles the sclerotic hyperplasia of non-syphilitic origin. [F. J. K.]

3.—Nicols discusses the existence of immunity after enteric fever, and believes that at the present time proof is wanting to show that such immunity occurs after an attack of typhoid fever. He holds that the teachings of sanitary science point out many ways by which the spread of the disease may be controlled. [F. J. K.]

4.—Latham writes upon the pathology and treatment of rheumatoid arthritis. He clearly points out the fact that post-mortem records show that the spinal cord and the sympathetic ganglia have never been examined by modern methods; therefore, the question as to the existence of organic lesions in these parts is still unanswered by pathologists. The author believes that clinical investigation points strongly to the presence of morbid changes in the nervous system. Neuralgic pains occur early in the course of this affection, thus pointing strongly to the neurotic character; and not unfrequently migraine, worry, fright or shock appear to be exciting factors. Muscular atrophy develops so rapidly that this change can hardly be attributed to disuse; indeed, in some instances the atrophy precedes the arthritis. The author emphasizes that it is not unreasonable to assume that spinal congestion or chronic myelitis, chiefly affecting the ganglion cells of the anterior horns, but in some instances the posterior horns, may produce rheumatoid arthritis. From the standpoint of treatment, in the earlier stages of rheumatoid arthritis, the author thinks that continuous counter-irritation of the spine is a valuable therapeutic measure. Counter-irritation to the spine is only of service in the advance stages of the disease, in relieving the patient of pain, during an exacerbation of the

mischiefs, thereby preventing further extension of the disease. [F. J. K.]

5.—F. B. Jessett reports an interesting case of a woman aged 56 years when he first saw her 11 years ago. At this time she was suffering with all the symptoms of pyloric stenosis, vomiting after meals and enormous distension of the stomach accompanied by emaciation. At that time the abdomen was opened and a mass was found as large as a cocoanut involving a large area of the stomach, and as resection seemed impossible, a gastro-enterostomy was done. The patient improved at once, the tumor which had before been readily palpated through the abdominal wall gradually disappeared, and the patient soon regained her strength and health. 11 years after the operation the patient died of apoplexy. A post-mortem showed a contraction of the stomach at the former seat of the growth which resulted in the formation of an hour-glass stomach. The anastomosis has been made with the pyloric pouch and the opening was quite free, through it passing nearly all of the stomach contents, since the pyloric orifice was very much contracted. The opening between the two portions of the stomach at the seat of contraction was so small as to scarcely admit the passage of one finger. Jessett is unable to explain the disappearance of this mass which at the time of the first operation seemed malignant. [J. H. G.]

6.—George Flux, in speaking of the administration of anesthetics, urges upon anesthetists the consideration of the fact that it is the atmospheric air which acts as the conveying agent for the anesthetic; and that the depth of the anesthesia and effect of the anesthetic will depend upon the amount of dilution with atmospheric air. If the inhaler is placed tightly over the face and the air breathed by the patient pass through the inhaler, then of course much more effect of the anesthetic is obtained, and, on the contrary, if air is allowed to pass between the inhaler and the patient's face, then very little of the vapor is carried into the patient's lungs. Hence, it is maintained, that the amount of anesthetic used is no index as to the extent of the anesthesia, but rather the way in which it has been administered. [J. H. G.]

7.—Green reports three cases of acute ascending paralysis. Two of the case terminated fatally, but post-mortem examinations were not made. [F. J. K.]

8.—David Newman, in continuing the discussion of the history of renal surgery, speaks first of the history of the operation of nephrorrhaphy, which was performed by Dowe, of New Orleans, in 1874. Incision of the kidney for relief of pain was recommended first by Tiffany, of Baltimore, in 1885. Resection of the kidney was first done by Czerny in 1887, and since then has become an established operation in renal surgery. The various methods of anastomosing the ureters is next described, and also operations for stone in the ureter, and for the relief of stricture and valvular obstruction of the ureter. [J. H. G.]

NEW YORK MEDICAL JOURNAL.

1. The Early Diagnosis of Ectopic Gestation. ANDREW F. CURRIER.
2. The Use of Hot-water Vaginal Injections. JAMES HAWLEY BURTENSHAW.
3. A Case of Dystinuria ending in Recovery. JOHN REID.
4. Acute Spinal Ataxia (Nontabetic) and its Relation to other Forms of Acute Ataxia. CHARLES L. DANA.
5. The Pathology of Intra-uterine Death. NEIL MACPHRATTER.
6. Grippe, Pneumonia and Insanity. EMILE ARONSON.
7. Notes on the Treatment of Diphtheria, Based on the Methods of the New York City Hospital. WM. L. SOMERSET.

1.—Currier remarks that ectopic gestation should include gestation only within the fallopian tube proper, the interstitial form being, strictly speaking, uterine. The symptoms which determine the diagnosis of tubal gestation

may be divided into the ordinary and the extraordinary. The ordinary include the enlargement of the breasts, with increased prominence of the veins and enlargement of the papillae in the areola that surrounds the nipple, the bluish discoloration of the vaginal mucosa, the softness of the tissue of the vagina and the uterus, non-appearance of the menses, irritability of the stomach, possible nausea and vomiting, increase in the size and change in the contour of the uterus, and increase in the secretion of the glandular structure of the vagina and the uterus. The extraordinary signs should be regarded as confirmatory of the ordinary. They are not always present, or always present at the same period, or always of equal intensity and significance. The most important is hemorrhage. It is most likely to occur, and occurs most early, in those cases in which the seat of the gestation is the fimbriated extremity of the tube. It is least likely to occur when the oval sac is near the middle of the tube. Next in importance to bleeding is pain. It is not always present, it is usually paroxysmal, sharp and darting, and inclines the patient to relax the thigh muscles and flex the thighs upon the abdomen. The third diagnostic point consists in the presence of the pelvic tumor, which is usually best determined by examination per rectum. The passing of decidual membrane by the vagina, pulsation of the vaginal arteries, and various other signs are all of minor importance. [W. A. N. D.]

2.—Burtenshaw states that there is no therapeutic measure so frequently misapplied, so thoroughly abused, or so imperfectly understood as the **hot-water vaginal injection**. Employed conscientiously and in accordance with the rules of common sense it is one of the most valuable remedies at our command; employed as it usually is it is capable of doing infinite harm. He suggests the following directions for the therapeutic douche: 1. Use a large sized fountain syringe or douche-can attached to a support 3 or 4 feet above the body. 2. Always lie flat on the back when taking a douche with the hips slightly elevated and the shoulders depressed. 3. Always use at least 3 gallons of plain water as hot as can be borne (at a temperature at from 107° to 120° F. for each douche. 4. Take the injection twice daily, morning and evening, except on the 2 days preceding and the 2 days following the menstrual period, when it should be omitted. 5. Rest for half an hour or an hour in a recumbent position after taking each douche. Large hot-water vaginal irrigations should never be employed by healthy pregnant women for the reason that they reduce the bactericidal power of the vaginal secretion. Reclus asserts that the use of hot water enemata in pelvic inflammations is much to be preferred to the vaginal douche. Burtenshaw has made use of this method in but a few cases, and not with entirely satisfactory results. [W. A. N. D.]

4.—Dana gives the following summary in his article on **acute spinal ataxia (non-tabetic), and its relation to other forms of acute ataxia**:—(1) Acute ataxia occurs occasionally in tabes dorsalis, but is associated usually with characteristic symptoms. (2) Acute non-tabetic spinal ataxia occurs as a manifestation of spinal syphilis or senile arterial changes, and shows itself by a sudden onset of temporary motor weakness and bladder troubles, great ataxia, and minor sensory disorders. It may affect only one extremity, but usually affects the lower limbs. The tendency is to nearly complete recovery. (3) Acute bulbar or bulbocerebellar ataxia occurs as a sequel of some acute infection, and is usually the beginning of a form of multiple sclerosis. (4) Acute neuritic ataxia occurs as the result of multiple neuritis of the sensory type. It is usually in the non-alcoholic forms of neuritis, especially those due to metallic poisons, like arsenic, or to diphtheria. [T. M. T.]

5.—Macpratter has made a most extensive study of the **pathology of intra-uterine death**. He remarks that morbid influences in the uterus, the embryo, or its appendages, or general or local constitutional perversions may render it absolutely impossible for a viable fetus to be born. An investigation into all the conditions and various circumstances leading up to and producing uterine death is surrounded frequently by innumerable difficulties. He emphasizes the importance of investigating the condition of the male parent in those cases in which a woman is unable to

carry a fetus to the full term of gestation. The father may be too old or too young to impart the essential potency to the fecundatal fluid. Certain paternal diseases may have a similar effect, the fetus not receiving the necessary amount of vitality to continue the development of the product. It has been demonstrated conclusively that a woman may abort consecutively and yet be parentally fertile. Undoubtedly the fault here lies in the husband. Occasionally this defect may be congenital, but more frequently it is acquired. It is well, in investigating the causes of intra-uterine death to examine the male parent for non-descent of the testicle. Inflammation of the seminal glands, either acute or chronic, may be the cause of atrophy of the testicle and of the delicate tubuli. Syphilitic inflammation of the testicle has probably a greater tendency to be followed by deposit of fibrous exudate than the other varieties. Tuberculous disease of the testicle and seminal vesicle, and lead-poisoning in the male are both responsible for a certain percentage of the intra-uterine mortality. The causes attributable to the mother are much more numerous and complicated. All agencies which conduce to deterioration of the mother's health converge in this direction, as unhealthy surroundings, pernicious habits, unsuitable occupations, insalubrious climate, and extremes of heat and cold. The same may be said of artificial ways of dressing, tight lacing, irregular or late hours, lack of healthy exercise in the open air, anxiety, grief, or mental depression of any kind. Over-feeding, and over-stimulation have a harmful effect upon childbirth. It is difficult for an obese woman to become pregnant, and if she does there is great liability to miscarriage. That anemia will produce the death of a fetus is well recognized. Inter-breeding in animals, as well as in plants, has a tendency to produce mental and physical deformity, and even premature death in the former and immature leaves and seeds in the latter. The infectious diseases and pneumonia produce death of the fetus when the temperature goes above 104° F. and before the same temperature becomes fatal to the mother. Eclampsia is particularly fatal to the fetus, although whether it arises from the accumulation of urea, albumin, or some other deleterious substance circulating in the blood, is not known. For some unexplained reason there is a fertility among phthisical pregnant women which may be considered abnormal. The tendency to abortion in these women is nevertheless greater than in healthy women. Heart-disease is a much more serious condition in pregnancy than is phthisis, and syphilis in the mother is especially inimicable to the fetal life. The local pathological conditions that may interfere with the fetal nutrition and cause death include diseases of the fetal appendages, such as atrophy of the decidua, apoplexy into the decidua, and hemorrhages between the chorion and decidua, the latter forming one of the most frequent local causes of death of the embryo stage of gestation. This condition constitutes the well-known apoplexy of the ovum, and the fetal death in these cases is due to fatty degeneration of the tissues with consequent interference with the fetal nutrition. Deciduitis in its various forms is likewise responsible in a certain number of cases. Chronic diffuse endometritis may be considered the mildest type. Virchow describes a polypoid form; another well-known variety is the catarrhal, which constitutes the hydrorrhea of pregnant women, while the syphilitic form is exceedingly grave in its effect upon the embryo. Deciduoma malignum, according to Macpratter, may occasionally be the offending condition. Diseases of the chorion, such as the vesicular degeneration, is a rather infrequent cause of embryonic death. In this condition the chronic villi undergo a myxomatous change with rapid increase in size and total destruction of the normal placental and fetal tissue. Morbid conditions of the amnion may likewise be encountered, such as an excessive amount of the amniotic fluid or, the converse, absence of the proper quantity, constituting a so-called "dry labor." Placental disease which may effect the fetal life, may take place as a hemorrhage or apoplexy which by so separating the placenta from the uterine wall as to interfere with its function, will result in fetal death. Placenta previa and placentalitis, the latter syphilitic in origin, must not be overlooked. Various forms of degeneration of the placenta, such as fatty, calcareous, edematous, myxomatous and cystic are likewise responsible in certain cases. There may also be certain diseases attributable to the umbilical cord, such as coilings and twistings or the actual forma-

tion of knots which constrict the vessels sufficiently to arrest the circulation. Among other causes of fetal death not already enumerated may be mentioned hydrocephalous and malformation of the child, rupture of the uterus, deformities of the pelvis, and ovarian and fibroid tumors. Macphatter closes his paper with a few suggestions as to the treatment of the various conditions mentioned. [W. A. N. D.]

7.—Somerset carries out the following special treatment in a child that is carrying an intubation tube:—(1) Careful attention must be given to the drainage of the air passages, and irrigation of the throat is not desirable; (2) All mucus and membrane coughed up, but not expelled, should be removed by the finger; (3) Nasal irrigation is permissible; (4) Feeding, whenever possible, should be done in the ordinary way, and if the child cannot swallow in the normal position, lavage is usually the remedy. If lavage is contraindicated, semi-solid food may be given; (5) Internal medicine should be reduced to a minimum. If the case is complicated by an exudation of especially tenaceous mucus, the inhalation of medicated steam should be tried; (6) Absolute rest is essential, and morphine should be used if necessary; (7) The tube should be used just as short time as possible. In early cases it should be removed by the fifth day. Children under two years old generally carry the tube two weeks or longer. [T. M. T.]

MEDICAL RECORD.

April 26, 1901.

1. The Toxemia of Pregnancy: its Diagnosis and Treatment. S. MARX.
2. Faith Cures and the Law. JOHN B. HUBER.
3. Report of Three Cases of Malignant Endocarditis: One following Measles, another Typhoid Fever in a Child and Simulating Splenic Lymphatic Leukaemia, and another Terminating in Recovery. ALBERT E. ROUSSEL.
4. Strangulated Hernia in Infants: Description of a Hitherto Unrecognized Cause and Seat of Strangulation. ALEXIS V. MOSCHCOWITZ.

1.—S. Marx discusses the toxemia of pregnancy and its diagnosis and treatment. He concludes that the toxemia is a complex condition depending on more than one factor. Many women go to term with albuminuria, without symptoms referable to toxemia. When such symptoms arise they are not caused by the albumin present, but by faulty urea secretion. In the most desperate and malignant cases there are found neither albumin nor casts. Urea is always found markedly diminished in the so-called "true toxemias" of pregnancy, or urinemia. Finally Marx makes a strong plea for a regular and methodical cause of urea examinations in all cases of toxemia, or for the relegation to secondary importance of the time honored examination for albumin. Progressive diminution of urea excretion, with or without albuminuria, is the sole indication of premature labor, which is especially indicated when conscientious medical treatment fails. [T. L. C.]

4.—A. V. Moschcowitz reports 2 cases of **strangulated hernia in infants** with a description of a hitherto unrecognized cause and seat of strangulation. The author believes that the comparative rarity of strangulated hernias in infants of three and four months, would alone be almost sufficient justification for the publication of his two cases. His chief reason is the heretofore unrecognized location of the condition **low down in the scrotum**, which occurred in both of his cases. As a rule the strangulation occurs in all hernias at the external ring, or the internal ring, or the neck of sac. The few exceptions of this general rule are caused by newly-formed inflammatory bands and adhesions, or more rarely, but openings in the prolapsed omentum. He gives a critical review of the reported cases regarding this point, and in order to explain the unusual conditions present in his cases goes back to the developmental stage of the organs in this region. In the course of development the process us vaginalis may being the shutting off of the normal tunica vaginalis, but the process

may stop before it is entirely completed. The result will be a sac of the usual congenital variety with the important difference that it will be constricted in its lower portion. In other words, the sac may not improperly be compared to an hour-glass open at its top. The size of the two halves varies, depending upon the different theories which have been proposed as regards the exact mode of development. He believes that in many cases of strangulating by the neck of the sac may be accounted for by the theory of Lockwood, who states that there seems to be a strong tendency for the processus vaginalis to close in two places which are some distance apart, namely just above the testicle and near the internal ring. [T. L. C.]

MEDICAL NEWS.

April 26, 1901. (LXXVIII, No. 16.)

1. An Historical Sketch of the Department of Medicine and Surgery of the University of Michigan.
2. Some Errors in the Examination of Urine. LOUIS HEITZMANN.
3. Acute Traumatic Malignancy. WILLIAM B. COLEY.
4. Epistaxis. CHARLES N. COX.

2.—Heitzmann, in his article on **Some Errors in the Examination of Urine**, considers the heat test for albumin the most reliable, provided that acids are used to differentiate between phosphates and albumin. He recommends the use of equal parts of glacial acetic acid and water instead of nitric acid on account of the latter's strength, stating that in urine with small quantities of albumin it would not precipitate the albumin, but dissolve it out. The acetic acid must not be pure for the same reason. He claims epithelial, blood, granular, fatty and waxy casts as true casts, the first three being found in acute conditions, the latter three in subacute and chronic inflammation. Granular casts are, as a rule, never found until the inflammation has lasted six weeks or two months, although exceptionally, especially in cases of nephritis after contagious diseases, they can be seen in small numbers in the 2d or 3d week of the kidney disease. Fatty casts, when present in large numbers, mean chronicity and fatty degeneration of the kidney. Waxy casts indicate a waxy or amyloid degeneration of the kidney and are found in chronic constitutional diseases. The sizes of casts vary greatly, the most narrow being those from narrow or looped tubules; the second size, from the larger convoluted tubules; while the larger ones come from the straight collecting tubules. The cylindroids or mucus-casts he describes as casts made up of mucus threads which may be derived from any portion of the genito-urinary tract and are therefore not diagnostic of nephritis. Great care must be taken not to mistake these casts for hyaline, as is not an infrequent occurrence. He does not favor the use of the centrifuge, and believes that allowing the urine to stand six to twelve hours previous to microscopical examination is to be preferred, except in case of tubercle bacilli. He concludes by saying that the diagnosis of nephritis does not depend necessarily upon the presence of casts, since they are almost invariably absent in interstitial nephritis. Pus corpuscles, red blood discs and kidney epithelia are sufficient for a diagnosis. [T. M. T.]

3.—Coley states that the **relationship between antecedent trauma and the development of sarcoma or carcinoma** can be most rationally explained on the theory that such tumors are infectious, or of micro-parasitic origin. The similarity between sarcoma and diseases known to be of infectious origin is very striking. The clinical evidence, aside from the bacteriological or pathological, points more and more strongly to specific infection as a cause of sarcoma, and he especially instances the close resemblance of the histology of tuberculous sarcoma. He suggests that the most probable explanation is that the microorganism exists latent in certain subjects under normal conditions. The local trauma diminished the vitality of the

tissues and hence their resisting power and the germs, previously innocuous, gain a foothold and develop. He concludes as follows:—(1.) Trauma is a very important factor in the causation of malignant tumors; (2.) The relationship between injury and malignant tumors furnishes additional and by no means unimportant evidence in support of the infectious origin of such tumor. [T. M. T.]

4.—Cox holds that the majority of nasal hemorrhages are due to some intranasal lesion and the most frequent injury which gives rise to epistaxis is a blow or fall upon the nose resulting in rupture of some of the minute vessels of the mucous membrane lining the nose. The most frequent seat is the triangular cartilage of the septum just within the vestibule. When bleeding occurs in this locality it is not necessary to pack, as the bleeding point can be seen and easily reached. Deviation or spur of septum, varicose enlargement of the veins of the septum, minute angiomas, intranasal growths are all apt to produce bleeding. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

April 18, 1901.

1. The Opinion Evidence of Medical Experts. JOHN D. McLAUGHLIN.
2. The Umillian Murder. HERBERT B. PERRY.
3. Upon what Sort of Information shall a Medical Examiner Hold a View? H. M. CULLS.
4. Leukocytosis and Typhoidal Perforation. From the Medical Clinics of the Montreal General and Royal Victoria Hospitals. COLIN K. RUSSELL.

1.—When testifying to his opinion, based either on facts that he has himself observed on admitted facts, or upon some hypothesis; expressing the judgment of a scientific man, ready to submit it to the opinion of the members of his own profession, to the cross-examination of council, publicly and to the world, the physician evokes an interest that rarely surrounds a witness under any other circumstances. Few theories, however fantastic need go unchampioned at present in the condition of medical expert testimony and it is the experience of lawyers that to testify as an expert is becoming more and more repugnant to those physicians whose evidence would be of the most value. But who will say that the conditions, of which certain cases cited by McLaughlin are but illustrations, are not largely owing, rather to the defective method of the law, than to the imperfections of science or that we are confronted with a state of things that it is impossible to ameliorate? Surely the fault cannot be laid at the door of science. Wherever the experts in the cases referred to were in contradiction, one of them was right and the other wrong. It would seem that it is the duty of the law to establish as many barriers to the progress and triumph of the wrong side of expert testimony as is humanly possible. The author points out on what insufficient grounds some men have been heard as expert witnesses in certain trials. It is difficult to perceive how an expert's position in relation to facts differs from that of a judge in respect to the law. In a law judge, learning and disinterestedness are the two requisites that are conceded by every one to be preeminent, and the faintest trace of prejudice, bias or partisanship disqualifies a person from becoming a judge. Neither little learning nor much bias, under our practice, disqualifies the expert. After describing the method of procedure in Germany the author says that he would not be thought to advocate the German method but that he underlying principle of the law relating to expert testimony is that the expert should not be a partisan. [J. M. S.]

2.—Perry describes the wounds on the body of a murdered man, whose corpse was found 3 months after he had been killed. The man accused of the murder was sitting in the kitchen of a farm-house, handcuffed to an officer. The district police officer came in suddenly and asked the accused what he had done with the head of his victim. The accused said the he "did not know," but his pulse,

which had been beating at the rate of 80 per minute suddenly increased to 120. [J. M. S.]

4.—Russell reports 6 cases that show that the leukocyte count may vary greatly in typhoid fever. Even where no complication is evident the leukocytes may number 15,000. Again, when certain complications, other than perforation, exist the leukocyte count may be markedly above normal. When pain and tenderness in the abdomen come on suddenly in the course of typhoid fever and there is absence of definite complication such as cholecystitis the presence of leukocytosis renders exploratory incision justifiable and advisable in order to obviate the danger of fatal issue from too great delay. [J. M. S.]
